RABIES

Human rabies is an encephalitic illness caused by the rabies virus, usually transmitted by an animal bite. It produces a fatal encephalitis, although the long latency between animal bite exposure and occurrence of neurologic symptoms may sometimes obscure the diagnosis.[16]

EPIDEMIOLOGY AND PATHOBIOLOGY

Rabies is a rare illness in the United States and developed world. However, initially unsuspected cases have been transmitted via trivial bites by infected bats, which are widely distributed in every state in the United States except Hawaii. Rabies virus variants in bats are now responsible for most recent human cases in the United States and Canada.

Canine rabies is still endemic in much of the developing world, including Africa, Latin America, Eastern Europe, and Asia, and most human rabies cases worldwide occur because of untreated dog bites from endemic areas. Rare cases of transmission of rabies to transplant organ recipients have occurred in the United States.

The presence of Negri bodies (intracytoplasmic viral inclusions) in neurons of the brain stem, cerebellum (especially the Purkinje cells), or hippocampus defines rabies pathologically. These inclusions are often not present, and more sensitive detection of antigen by immunohistochemistry aids in the pathologic diagnosis.

CLINICAL MANIFESTATIONS

Human rabies usually develops 20 to 90 days after a bite, although rarely disease develops after only a few days or after a year or more following bite exposure. Multiple bites and facial bites are associated with shorter incubation times.

Nonspecific prodromal symptoms include fever, chills, malaise, fatigue, insomnia, anorexia, headache, and irritability. In most patients, migratory pain or paresthesias will develop in the limb that was affected by the bite. Following the prodromal illness, an encephalitic form develops in about 80% of patients and causes behaviors ranging from episodes of agitated arousal to quiet lethargy. Fever is a common accompaniment but not universal at this phase. Disinhibition of brain stem reflexes leads to hydrophobia with laryngospasm and an inability to deal with salivation, swallowing of water, or other oral intake. When the brain stem encephalitis affects the bulbar, cardiovascular, and respiratory centers, autonomic dysfunction, cardiopulmonary complications, and respiratory failure occur.

Another form of rabies that affects up to a third of patients is known as paralytic rabies. This form of rabies is manifested as acute flaccid paralysis, which may be multifocal and affect the limbs and the bulbar musculature, thereby resembling poliomyelitis (Chapter 349) because of its multifocality. It can be confused with Guillain-Barré syndrome (Chapter 388). Paralytic rabies typically occurs in conjunction with febrile encephalitis.

DIAGNOSIS

Findings on spinal fluid analysis may be abnormal in human rabies. A lymphocytic pleocytosis, usually less than 100 white cells/μL, is found in more than 50% of patients in the first week of illness. The CSF protein concentration usually is mildly elevated, and the glucose level is usually normal.

Imaging of patients with rabies is sometimes useful. MRI may show gray matter involvement, particularly involvement of the brain stem and deep gray matter structures, with increased T2 signal, commonly without enhancement. Spinal cord MRI in patients with paralytic rabies may show multifocal increased T2 signal mimicking acute disseminated encephalomyelitis. Involvement of brain gray matter, including the hippocampus and basal ganglia structures, indicates the gray matter predilection and often bilateral involvement of supratentorial structures. However, MRI cannot be relied on to exclude rabies.

Rabies RNA can be detected by PCR testing of spinal fluid, saliva, or brain tissue. A positive result confirms the diagnosis, but the exclusionary value of negative results is unknown. Serum antibodies against rabies virus are not usually present in unimmunized patients until the second week of illness, and patients can die before having a detectable serum antibody level in serum or in spinal fluid, but its absence is unreliable in excluding the diagnosis. Staining of a skin biopsy sample taken from an area near the nape of the neck for rabies antigen in the sensory nerves can confirm the diagnosis of rabies.

TREATMENT

Rabies postexposure prophylaxis includes local wound cleansing, passive immunization with immunoglobulin, and active immunization with rabies vaccine. Once rabies encephalitis is manifested, however, it is unclear whether vaccination, although regularly used, has any role in improving outcome. Antiviral therapy and a variety of immunotherapies, including ribavirin and interferon alpha, have been tried in the treatment of rabies, usually without success.

Health care workers can occasionally have high-risk exposures related to broken skin contact or mucosal splash with the patient's secretions. Given the lack of documented human-to-human rabies transmission, postexposure prophylaxis for contacts of patients with rabies is rarely indicated but can be decided on a case-by-case basis after consultation with local or state health officials. An mRNA vaccine is currently being tested for primary prophylaxis in high-risk individuals.

PROGNOSIS

Although one patient has survived with the use of therapeutic coma without vaccination, subsequent reports of patients treated in similar fashion have been associated with a fatal outcome. Treatment is otherwise supportive, and outcome is essentially always fatal.

COVID ENCEPHALITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Coronavirus-2019 disease (COVID-19; Chapter 335) from infection with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) can cause encephalitis, especially in patients with serious COVID infection.[17] The incidence of encephalitis as a complication of COVID-19 is about 0.2%,[18] However, several autopsy studies of patients with encephalopathy as a consequence of COVID infection have revealed little evidence of direct viral infection of the brain.[19] Instead, prominent microglial activation, particularly affecting the brain stem, has been noted without evidence of direct viral infection or damage. This phenomenon has been referred to as parainfectious (inflammation occurring at the time of the infection without viral infection of brain cells) or postinfectious (viral-directed immunity cross-reacting with nervous system tissue), thereby suggesting immune mechanisms and possibly vascular mechanisms as the cause. One concept is that the microvasculature is affected by the cytokine storm, thereby leading to microthrombosis, hemorrhage, and ischemic infarcts from small-vessel disease in the brain.

DIAGNOSIS

The spinal fluid may show a low-grade pleocytosis, and virus may be detected by PCR. A small percentage of patients have frank focal clinical and imaging abnormalities suggesting acute necrotizing encephalopathy, limbic encephalitis, acute disseminated encephalomyelitis, and acute hemorrhagic leukoencephalitis on a parainfectious or postinfectious basis.[20]

TREATMENT

Post-COVID encephalitis may treated as for autoimmune encephalitis (see later).

PROGNOSIS

Many COVID-19 patients will have prolonged neurologic symptoms, including include brain fog, cognitive symptoms, headache, anosmia, and fatigue. It is unclear whether these phenomena are related to encephalitis or to consequences of microvascular disease and cytokine effects on the brain.

RARE VIRAL CAUSES OF ENCEPHALITIS

Lymphocytic choriomeningitis (Chapter 381) virus is a human infection acquired from mice. Typically, humans acquire the infection by contact with food or dust that is contaminated by excreta of the common house mouse. Most commonly, human disease occurs in winter, when the natural host tends to move indoors. It also can be acquired due to laboratory exposure by human caretakers.

The mumps virus (Chapter 340) is typically acquired by the respiratory route. Infection can occur throughout the year, but the incidence is higher during the spring. Although mumps virus infects both sexes equally, meningoencephalitis develops in males three times more frequently than in females. Vaccination programs in the United States have made mumps encephalitis rare, though unvaccinated populations may bring this disorder back to prominence.

AUTOIMMUNE ENCEPHALITIS

Autoimmune encephalitis is increasingly recognized as a treatable cause of brain dysfunction distinct from infectious encephalitis. It can be caused by a number of autoantibodies and is also an infrequent complication of treatment with programmed cell death-1 checkpoint inhibitors.

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoimmune encephalitides are responsible for about 25% of all cases of encephalitis. Autoimmune encephalitis is a complex series of disorders that can mimic infectious encephalitis or present with neurocognitive disorders and seizures alone. An ever-increasing list of autoantibodies has been associated with encephalitis (Table 383-3).[21] Some disorders are paraneoplastic disorders,[22] with autoimmunity directed against cancer also affecting the nervous system. However, primary autoimmune encephalitis without detectable cancer can be associated with similar autoantibodies, and autoimmune encephalitis can be a complication of treatment with programmed cell death-1 checkpoint inhibitors.[23] Encephalitis also can occur with autoimmune antibodies associated with systemic disease, including Hashimoto encephalopathy (Chapter 207), encephalopathy associated with Sjögren syndrome (Chapter 247), and rheumatoid arthritis–associated meningoencephalitis (Chapter 243).

In general, the autoimmune encephalitides can be divided into primary, in which the autoantibody is directed against a central nervous system antigen, or secondary, in which the autoantibody associated with the encephalitis is directed against a systemic antigen and associated with systemic autoimmune disease. In both types, the antibody may either be pathogenic or be a marker

TABLE 383-3 AUTOIMMUNE ENCEPHALITIS AND ASSOCIATED NEURAL ANTIGEN TARGETS

NEURAL ANTIGEN	ASSOCIATED NEOPLASIA OR SYSTEMIC DISEASES	ENCEPHALITIS CLINICAL PHENOTYPE
Hu or ANNA-1	Small cell lung carcinoma	Limbic encephalitis
Ri or ANNA-2	Breast, gynecologic, lung, or bladder cancer	Brain stem/cerebellar encephalitis
Ma2	Testicular seminoma	Limbic encephalitis, brain stem encephalitis
GAD65	Thymoma, small cell lung cancer, breast cancer, diabetes	Cerebellar encephalitis, stiff person syndrome
NMDA-R	Ovarian teratoma	Encephalitis
AMPAR	Thymoma, small cell lung cancer	Limbic encephalitis
GABA A receptor	Infrequent, thymoma	Limbic encephalitis
GABA B receptor	Small cell lung cancer	Limbic encephalitis
mGluR5	Hodgkin lymphoma	Encephalitis
GlyR	Infrequent thymoma	Limbic encephalitis, PERM
VGKC (voltage-gated potassium channel complex)		
LGI-1	Neuroendocrine tumor, thymoma	Limbic encephalitis, faciobrachial seizures
CASPR 2		Limbic encephalitis, Morvan syndrome
DPPX	Megacolon, rare B cell neoplasm	Encephalitis, PERM
KLHL11	Testicular seminoma	Cerebellar encephalitis, hearing loss
CRMP 5	Small cell lung cancer, thymoma	Encephalomyelitis; limbic encephalitis
Amphiphysin	Breast cancer, small cell lung cancer	Limbic encephalitis, encephalomyelitis
PCA-1	Small cell lung, breast, or ovarian cancer	Cerebellar/brain stem encephalitis
MOG	Rare ovarian teratoma	Encephalomyelitis
AQP4	Rare adenocarcinoma	Neuromyelitis optica, brain stem encephalitis
GFAP	Rare ovarian teratoma	Encephalomyelitis

AMPAR = α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; ANNA = antineuronal nuclear antibody; AQP4 = aquaporin 4; CASPR 2 = contactin-associated protein-like 2; CRMP 5= collapsin response-mediator protein 5; DPPX = dipeptidyl peptidase-like protein; GABA A receptor = ɣ-aminobutyric acid-a receptor; GABA B receptor = ɣ-aminobutyric acid-b receptor; GAD65 = glutamic acid decarboxylase 65-kilodalton isoform; GFAP = glial fibrillary acidic protein; GlyR = glycine receptor; KLHL11 = Kelch-like protein 11; LGI 1 = leucine-rich glioma-inactivated protein 1; mGluR5 = metabotropic glutamate receptor type 5; MOG = myelin oligodendrocyte glycoprotein; NMDA-R = NMDA receptor; PCA-1 = Purkinje cell cytoplasmic antibody; PERM = progressive encephalomyelitis with rigidity; VGKC = voltage-gated potassium channel complex.

of autoimmunity associated with encephalitis. Additionally, the typical phenotype of autoimmune encephalitis can occur with no identifiable autoantibody.

CLINICAL MANIFESTATIONS

The three characteristic clinical syndromes of autoimmune encephalitis are limbic encephalitis, a cerebral cortical generalized encephalitis similar to what is associated with *N*-methyl-D-aspartate (NMDA)-receptor antibodies, and brain stem encephalitis. Other clinical phenotypes associated with paraneoplastic autoimmunity include rapidly progressive cerebellar encephalitis, neuromyelitis optica, and opsoclonus myoclonus.[24] Less well-defined encephalitis with encephalopathy, behavioral abnormalities, neurocognitive changes,[25] and evidence of brain inflammation identified by spinal fluid pleocytosis can also occur.

The clinical presentation is typically acute or subacute alteration of mental status characterized by change in behavior, memory, and awareness. Seizures also are common.

NMDA receptor can be paraneoplastic in association with ovarian carcinoma, but it can be found after apparently successful treatment of viral encephalitis and in other patients as an autoimmune disorder without known cancer. Otherwise unexplained NMDA-receptor autoimmune encephalitis has been associated with a female predominance, psychosis, and abnormal behavior in adults. Because of the frequent psychiatric symptoms at onset, correct diagnosis may be delayed. The diagnosis requires specialized testing with detection of NMDA-receptor antibodies in the spinal fluid of affected patients.

DIAGNOSIS

An expanding number of IgG autoantibodies can help in the definitive diagnosis of the specific type of autoimmune encephalitis and also for guiding subsequent evaluation, including the search for an occult malignancy and the potential escalation of immunotherapy.[26] Such testing is critical because a variety of psychiatric, neurodegenerative, and functional disorders can be misdiagnosed as autoimmune encephalitis.[27] In limbic encephalitis, the CSF often shows lymphocytes (5 to 100/μL) but no identifiable infection. Antibody testing of CSF and often blood can identify the underlying antibody.[28]

Malignancy is the cause in at least 95% of patients who have anti-Hu (small cell lung carcinoma [Chapter 177]) or Ma2 (testicular seminoma [Chapter 185]) antibodies and in about 25% of patients who have high-titer anti-glutamic acid decarboxylase (GAD) antibodies (thymomas [Chapter 390] or small cell lung carcinoma [Chapter 177]). GAD antibodies are also found in patients with diabetes (Chapter 210) and other endocrine disorders. Other antibodies with a moderately high risk of malignancy include γ-aminobutyric acid (GABA) B (small cell lung cancer; Chapter 177), mGlu-R5 (Hodgkin lymphoma; Chapter 172), and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (thymomas [Chapter 390] and small cell lung cancer [Chapter 177]). In patients who have autoantibodies that are potentially linked to occult malignancy, whole-body computed tomography (CT) and, if possible, positron emission tomography (PET) should be performed.

In NMDA-receptor encephalitis, the CSF contains antibodies against the GluN1 subunit of the NMDA receptor. However, serum can have false-negative results. Some patients have underlying ovarian teratomas (Chapter 184). Neuroimaging with a brain MRI scan of the head may show focal areas of encephalitis or be normal. Because NMDA receptor encephalitis is treatable, it is important to recognize when it has been triggered by viral injury, such as prior herpes simplex encephalitis.

Some systemic antibodies that are associated with autoimmune encephalitis (e.g., GAD65 and TPO antibodies) are common in the population at large and are not a sign of disease by themselves. Hashimoto encephalopathy is most controversial because of frequent occurrence of thyroid peroxidase (TPO) antibodies in the population (Chapter 207), and the nonspecificity of the encephalopathy.[29] However, patients with laboratory signs of spinal fluid inflammation and high serum levels of TPO antibodies probably have autoimmune encephalitis. Sjögren syndrome (Chapter 247) can cause a variety of neurologic consequences, one of which is meningoencephalitis associated with behavioral change. Rheumatoid arthritis (Chapter 243) affects the pachymeninges as well as the leptomeninges and brain in selected patients.[30]

TREATMENT

No standardized treatment exists for autoimmune encephalitis.[31] The goal of initial treatment is to provide the maximum response that can be obtained with an immunotherapy regimen.[32] The intensity and duration of the initial phase of treatment depends on the clinical syndrome, presence or absence of underlying cancer, and severity of illness. Patients who are clinically unstable may require a rapid escalation of treatment strategies.[33]

Most experts recommend intravenous methylprednisolone (1000 mg intravenously daily for 5 days). Intravenous immunoglobulin (400 mg/kg every other day for 5 days) may be used in patients who do not tolerate steroids. Therapy can be continued with weekly methylprednisolone or immunoglobulin for 6 to 12 weeks in an ambulatory setting.[34] Some experts will use a course of oral corticosteroids tapered over weeks to months instead. Other options include rituximab (1000 mg twice, 2 weeks apart) or tocilizumab (4 mg/kg every 4 weeks, then increased to as much as 8 mg/kg every 4 weeks based on the clinical response). Other regimens with anecdotal reports include cyclophosphamide, azathioprine, mycophenolate, methotrexate, anti-B cell antibodies, or anti-CD19 monoclonal intravenous antibodies. Plasma exchange may be used in patients with treatment-refractory disease or in patients with contraindications to other treatments.

PROGNOSIS

Prognosis for autoimmune encephalitic diseases vary widely, and no single statement can apply to this series of disorders.

384 NUTRITIONAL AND ALCOHOL-RELATED NEUROLOGIC DISORDERS

BARBARA S. KOPPEL, LOUIS H. WEIMER, AND MICHAEL DARAS

Vitamins and minerals, which are essential to cellular function, must be obtained from the environment because the body cannot produce them. They are necessary for embryonic and early development as well as the subsequent maintenance of metabolic function of both the central and peripheral nervous systems. Deficiencies can cause a variety of neurologic syndromes (Table 384-1), each with a well-described constellation of symptoms that are dependent on the location of the pathology within the nervous system, the duration of the deficiency, and the potential presence of multiple deficiencies or other risk factors, such as excess alcohol use.

Acquired vitamin deficiency (Chapter 199) can be caused by malnutrition (Chapter 197), malabsorption (Chapter 126), or increased demand owing to stress, sepsis (Chapter 94), chronic inflammatory conditions, renal dialysis (Chapter 117), infection, or other disease states. Even with adequate supply, inherited (genetic) conditions can produce neurologic dysfunction through various pathophysiologic mechanisms, including aberrant production of a necessary cofactor; impaired transport of a vitamin from the intestine, in the blood, or within the cell that needs it (e.g., mitochondria, neuron, glial cell); production of an enzyme from a vitamin cofactor, thereby resulting in metabolic dysfunction; or an epiphenomenon in a vitamin pathway. These gene disorders generally present early in life, even in neonates, although somewhat different presentations can occur in adolescence or adulthood. By comparison, acquired deficiency states may occur at any age and usually take months to years to develop. Exposure to alcohol, chemotherapy, cassava, or other neurotoxins in the setting of certain vitamin deficiencies (usually B_1) synergistically contributes to neuropathology. Genetic predisposition to variable metabolic rates also may explain why not all patients who consume the same food or ingest the same amount of alcohol develop deficiencies.

Malnutrition is the most common cause of vitamin deficiency in economically disadvantaged geographic locations, especially in seasons of famine due to drought or disease-induced crop failure or times of conflict or warfare. Overreliance on a single food source, particularly one that has lost its nutritional value—such as polished rice, untreated corn, or spoiled grain—can precipitate disease. In contrast, attempts to deal with obesity, such as consuming empty calories with little other nutritional value, following a fad diet, or undergoing restrictive bariatric surgery without guidance on the need for supplemental vitamins, can cause disease. Even when sufficient food supplies are readily available, malnutrition may be caused by inadequate consumption owing to mechanical obstruction from cancer of the mouth or gastrointestinal tract, unbalanced diets, fasting, anorexia, chronic nausea, or recurrent or persistent vomiting.

Iatrogenic causes include failure to feed patients who are comatose, patients who are not self-sufficient (from dementia [Chapter 371], brain injury [Chapter 368], or psychiatric illness [Chapter 362]), or patients who have dysphagia, as can occur following a stroke or spinal cord injury. Vitamin deficiency can also result from failure to include adequate amounts of vitamin and mineral supplements when parenteral or liquid enteral diets are used for an extended period (Chapter 198).

Malabsorption (Chapter 126) over long periods can cause deficiency of fat-soluble vitamins such as vitamin E and even substances with higher body stores, such as vitamin B_{12} and copper. As bariatric surgery has become more common in the treatment of morbid obesity (Chapter 201), patients who do not maintain their vitamin supplementation after bypass-type procedures or who continue to limit intake after undergoing restrictive procedures ("lap band," sleeve gastrectomy) are at high risk of vitamin deficiency syndromes, primarily early thiamine deficiency but also delayed cases of copper and B_{12} deficiency.

DEFICIENCY OF WATER-SOLUBLE VITAMINS

THIAMINE (VITAMIN B_1) DEFICIENCY

Thiamine is converted to thiamine pyrophosphate, which is a coenzyme required in glucose and lipid metabolism for energy production and in the synthesis of neurotransmitters from branched-chain amino acids (Chapter 199). Storage is exhausted after 2 to 3 weeks, and even sooner in conditions of high demand, such as pregnancy, lactation, or infection. Daily requirements of about 1 mg (0.33 mg per 1000 calories) can be obtained from food sources such as whole grains, legumes, meat, and fortified bread or cereals. Inherited dysfunction of thiamine transport mechanisms also can produce the same deficiency.

BERI-BERI

In developing countries, the most common manifestation of thiamine deficiency is beri-beri, which is characterized by a peripheral sensorimotor axonal neuropathy with numbness, paresthesias, or burning pain, occasionally accompanied[1] by peripheral edema from heart failure ("wet beri-beri"). Other causes of thiamine deficiency include reliance on foods in which the vitamin has been inactivated by processing (e.g., polished rice) or overcooking, or eating foods that contain thiaminase-producing bacteria (e.g., raw fish). Deficiency also contributes to the neuropathy caused by chemotherapy.

"Dry" beri-beri does not produce heart failure but has a prominent neuropathy that affects all nerve types (motor, sensory and autonomic) and produces subacute distal (because of its length-dependent process) weakness and burning pain that can mimic Guillain-Barré syndrome (Chapter 388). Progression usually occurs over weeks and can become advanced; rarely, a more insidious presentation can develop over months. Alcohol abuse can contribute to the nutritional deficiency but is not a required prerequisite.

WERNICKE ENCEPHALOPATHY

Thiamine deficiency also can result in Wernicke encephalopathy,[2] a syndrome characterized by the development and progression over days to weeks of confusion or delirium, abnormal eye movements, and ataxia as early as 2 weeks after thiamine stores have been depleted, especially in seriously ill patients. Wernicke encephalopathy occurs most often in the setting of poor nutrition or prolonged vomiting in patients with chronic alcohol abuse. Based on pathologic changes discovered at autopsy, only about 25% of cases are detected before death. Other at-risk patients include those with excessive vomiting from any cause,[3] including bariatric surgery[4]; patients with the acquired immunodeficiency syndrome (AIDS) or cancer; patients with cachexia and poor nutrition; or people who are chronically malnourished.[5] The symptoms and signs of Wernicke encephalopathy reflect the preferential dysfunction of brain regions that have a high demand for thiamine, a cofactor in energy-producing cycles, including the blood-brain barrier, anterior and centromedian thalamus, mamillary bodies, periaqueductal gray matter, superior and inferior colliculi, and floor of the fourth ventricle. The most common pathologic changes in these regions include neuronal swelling and microscopic hemorrhages, followed by gliosis. Rarely, the cerebral cortex and hypothalamus may be involved as well. Deficiency of α-ketoglutamate dehydrogenase activity in astrocytes leads to microglial activation and glutamatergic toxicity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The full triad of mental status change (delirium or coma), abnormal eye movements,[6] and ataxia occurs in only about one-third of cases. Acute symptoms may be provoked if intravenous (IV) glucose or food is given before thiamine has been replaced. Because a medical history may be unobtainable until the patient's confusion clears, physical signs of chronic alcoholism (e.g., gynecomastia, skin angiomata, palmar erythema, Dupuytren contractures, ascites, jaundice; Chapters 132 and 138) or of cachexia must be sought.

Mental status changes range from mild memory impairment and inattention to delirium and coma, often with apathy or abulia. Eye movement abnormalities include nystagmus, dysconjugate gaze, and gaze palsies (Video 384-1 and Video 384-2). Especially in alcoholic patients, ataxia can affect the limbs (legs more than arms), trunk, and gait. Nonalcoholic patients are more likely to have ocular dysfunction. Patients with Wernicke encephalopathy also can have autonomic and hypothalamic dysfunction, with bradycardia and hypothermia, as well as papilledema, optic neuropathy, seizures, and myoclonus.

In symptomatic patients, T2-weighted magnetic resonance imaging (MRI) can be normal but often demonstrates symmetrical increased signal owing to edema or hemorrhage in affected areas, most often periventricular thalamus, periaqueductal regions in the floor of the fourth ventricle or cerebellum, and in the mamillary bodies (Fig. 384-1). Low thiamine levels (<50 mg/mL) are common, although levels may be normal in about 10% of cases. Because thiamine deficiency disrupts carbohydrate metabolism, serum levels of lactate and pyruvate can be elevated.

ABSTRACT

Neurologic syndromes have been described in many vitamin deficiency states, with specific symptoms related to the site of the nervous system affected and the vitamin responsible. Examples include Wernicke-Korsakoff (thiamine, B_1), neuropathy (pyridoxine, B_6), myelopathy (B_{12} or copper), and ataxia (tocopherol, E). Alcohol causes neurotoxicity leading to dementia, seizures, neuropathy, and ataxia and can contribute to damage from vitamin deficiencies.

TABLE 384-1 VITAMIN AND MINERAL DEFICIENCIES

VITAMIN AND MINERAL DEFICIENCIES	NEUROLOGIC SYNDROME(S)	SUPPORTING TESTS	TREATMENT* REPLETION/SUPPLEMENTATION	CAUSES (OTHER THAN MALNUTRITION)
A (retinol)	Blindness from retinal or corneal damage, especially at night; ageusia	Visual fields, visual acuity Serum level <30-65 µg/dL	30,000 IU vitamin A daily × 1 wk or 60,000 µg × 2 days, repeated in 2 wk; then 5000-10,000 IU daily	Hypothyroidism, diabetes, renal or liver failure, bariatric surgery
B_1 (thiamine)	Wernicke encephalopathy: ataxia, nystagmus, ophthalmoparesis, confusion, delirium Korsakoff syndrome: amnesia, confabulation, impaired learning Beri-beri: axonal neuropathy with paresthesias, numbness, loss of distal reflexes	MRI: symmetrical lesions of midbrain (periaqueductal area), pons, hypothalamus, thalamus, cerebellum MRI: necrosis of mamillary bodies, dorsomedial and anterior thalamus Nerve conduction tests: decreased amplitude Serum thiamine level <20 ng/dL Decreased erythrocyte transketolase	Prevent by 100 mg PO daily before and after bariatric surgery, 100 mg IV before glucose administration or refeeding after starvation Treat Wernicke encephalopathy with 5 days of thiamine, 500-1000 mg IV or IM daily, until improvement stabilizes, then 250 mg daily for 3-5 days; then PO 100 mg daily or 100 mg IM monthly	Alcoholism, bariatric or other major GI surgery, prolonged vomiting, hemodialysis, diuretic treatment of heart failure, cachexia, 5-fluorouracil, other blockers of thiamine phosphate production
B_3 (niacin)	Pellagra: confusion, dementia, weakness, ataxia, spasticity, myoclonus, glossitis, dermatitis, photosensitivity	Erythrocyte NAD, plasma niacin, urinary N1-methylnicotinamide	Nicotinic acid, 50 mg PO tid or 25 mg IV tid; nicotinamide, 50-100 mg IM or 250-500 mg daily PO	Alcoholism, corn- or cereal-based diet, Hartnup syndrome, carcinoid syndrome
B_5 (pantothenic acid)	Dysesthesias, foot paresthesias, cramps, poor coordination	Deficient coenzyme A	5 mg PO daily	Severe malnutrition
B_6 (pyridoxine)	Neuropathy, sensory ataxia, depression, irritability Infantile and adult pyridoxine-deficient epilepsy	Plasma PLP <27 nmol/L; urinary 4-pyridoxic acid <3 nmol ↑ Homocysteine after methionine loading challenge ↑ α-AASA in urine, plasma, CSF	50-100 mg PO daily for neuropathy (preventive use if taking B_6 antagonist) 100 mg IV; then 15-30 mg/kg lifelong PO daily for infants, 100-200 mg PO daily for adult epilepsy	Diverticulosis, isoniazid, some anti-seizure medications, cycloserine, other antagonists Genetic defects in *ALDH7A1* gene for antiquitin (aldehyde dehydrogenase), pyridoxal synthesis Renal failure, homocystinuria
B_{12} (cobalamin)	Myelopathy with spastic paraparesis and sensory ataxia, peripheral neuropathy, optic neuropathy, memory loss, dementia; indirect contributor to stroke	Blood level <200 pg/mL ↑ Methylmalonic acid >145 nmol/L Intrinsic factor antibodies Megaloblastic anemia (bone marrow) Delayed somatosensory evoked potentials ↑ Homocysteine, total >12.5 µmol/L	IM B_{12}, 1000 µg daily for 1 wk, then weekly for 1 mo, then monthly; or oral B_{12}, 1000 µg daily; or nasal B_{12}, 500 µg weekly for lifetime if abnormal absorption, 50-100 µg daily if normal absorption	Achlorhydria, pernicious anemia, gastric or ileal resection, blind loop syndrome, sprue, HIV infection, nitrous oxide anesthesia (especially abuse), fish tapeworm, vegan diet
D (calciferol)	Proximal myopathy, often painful; cognitive impairment Secondary compression of spinal cord, plexus, or peripheral nerves from rickets or osteomalacia	25-(OH) vitamin D_3 level <10 ng/mL in urine Serum calcium ↑ PTH >54 pg/mL Osteopenia/osteoporosis on bone densitometry	Daily supplementation with 400 IU cholecalciferol (D_3) or 50,000 IU ergocalciferol (D_2) 1-3 times per week if malabsorption; use blood level to guide dosing or urine calcium excretion (should be >100 mg/day)	Lack of exposure to sunlight, including sunblock protection; chronic antiepileptic drug use
E (tocopherol)	Spinal and cerebellar ataxia, Babinski sign, ophthalmoplegia, peripheral neuropathy, retinitis pigmentosa	Vitamin E level <2.5 mg/L (normal, 6-15 with normal lipid level) ↑ A-β-lipoprotein levels, antigliadin antibodies Genetic analysis to rule out other spinocerebellar ataxias such as Friedreich ataxia	Supplement with 6-800 IU or 10-40 mg/kg daily, for ataxia of genetic causes. Water-soluble 20 mg/kg/day PO or 50-100 mg/wk IM α-tocopherol to normal serum level for malabsorption; 300 mg PO daily after bariatric surgery	Biliary atresia, celiac sprue, Genetic: ↓ α-tocopherol transport protein (8q13), microsomal triglyceride transfer protein
Folate	Dementia, B_{12} deficiency, stroke	↑ Homocysteine, plasma level <2.5 µg/L	1 mg 3 times daily until normal level, then maintenance of 1 mg/day Pregnancy: 1-4 mg/day during first trimester if taking a folate antagonist or at risk of neural tube defects	Malabsorption or use of antagonist (methotrexate) or antiepileptic medication
K (phytonadione)	Intracranial hemorrhage	INR or PT elevation	IM phytonadione at birth, maternal vitamin K for last month of pregnancy	Medication use that increases metabolism (e.g., phenytoin)
Copper	Myelopathy, neuropathy	Serum Cu <75 µg/dL, ↓ urinary Cu, ceruloplasmin <23 mg/dL MRI: ↑ T2 signal in cervical cord, dorsal column Mutation in *ATP7A* gene (Menkes disease)	Elemental Cu, 8 mg/day PO or 2 mg/day IV wk 1, 6 mg/day wk 2, 4 mg/day wk 3, 2 mg/day ongoing malabsorption Menkes disease: 250 mg copper histidine SQ bid, 1-2 mg in a multivitamin postbariatric surgery	Wilson disease, Menkes disease, alcoholism, malabsorption, gastric bypass, zinc toxicity
Magnesium	Seizures, encephalopathy	Serum magnesium <1.5 mg/dL, correct for low albumin	Magnesium sulfate IV or PO to normal level Avoid magnesium-wasting drugs	Alcoholism, especially beer Diuretic use
Potassium	Muscle weakness, chronic, acute	Serum potassium <3.5 mEq/L, ECG	IV or PO KCl until normalized	Diuretic use, bulimia

*Treatment doses not same as RDA, recommended daily intake.

AASA = aminoadipic semialdehyde; bid = twice daily; CSF = cerebrospinal fluid; Cu = copper; ECG = electrocardiography; GI = gastrointestinal; HIV = human immunodeficiency virus; IM = intramuscular; INR = international normalized ratio; IV = intravenous; KCl = potassium chloride; MRI = magnetic resonance imaging; NAD = nicotinamide adenine dinucleotide; PLP = pyridoxal-5-phosphate (active coenzyme of pyridoxine); PO = by mouth; PT = prothrombin time; PTH = parathyroid hormone; SQ = subcutaneous; tid = three times daily.

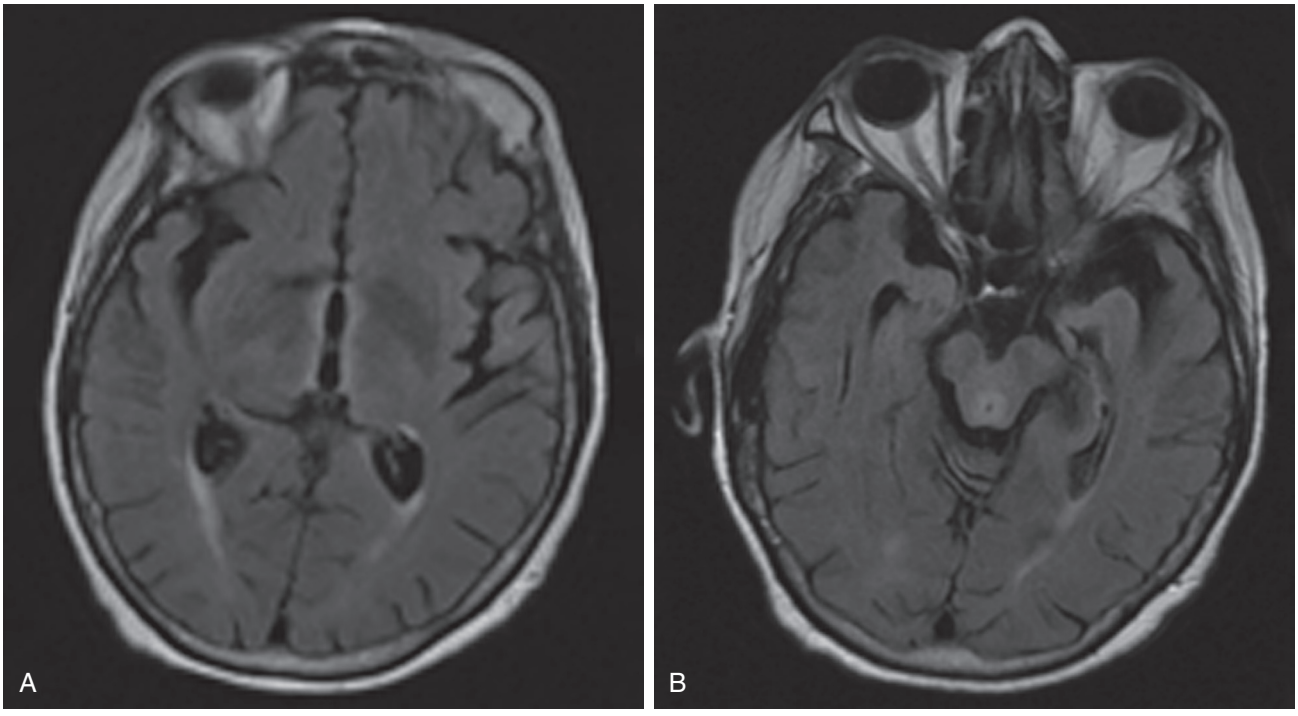

FIGURE 384-1. **Wernicke encephalopathy. A,** Magnetic resonance imaging axial FLAIR images show abnormal hyperintensity of bilateral medial thalami/periventricular third ventricle. **B,** Hyperintensity of tectum of the midbrain periaqueductal region.

KORSAKOFF SYNDROME

Korsakoff syndrome becomes apparent in up to 80% of patients who survive Wernicke encephalopathy. It is more likely to follow in the setting of alcoholism than in pure nutritional deficiency, thereby implying a synergistic mechanism that may be due to repeated episodes of alcohol withdrawal with associated glutamate neurotoxicity, compounded by lack of thiamine. The primary pathologic findings occur in the limbic system, especially the mamillary bodies, amygdala, and dorsomedial and anterior thalamus. Cortical involvement may be related to alcohol neurotoxicity rather than thiamine deficiency.

As the mental status changes of Wernicke syndrome improve, the delirious, confused state is followed by an amnestic state in which patients are often unaware of their memory impairment. Korsakoff syndrome can be reliably identified only when patients can cooperate with neuropsychological testing. It is characterized by retrograde and anterograde episodic amnesia, confabulation, and hallucinations. Occasionally, Korsakoff psychosis is present clinically or pathologically without documented episodes of Wernicke encephalopathy, perhaps because Wernicke encephalopathy went unrecognized.

The memory deficit, which precludes learning new information or acquisition of new memories, is disproportionately severe in relation to other aspects of cognitive function. For example, alertness, attention, social interactions, and motor learning (procedural memory) are generally well preserved. There may be mild disorientation with respect to time and place, and sometimes apathy and other emotional changes are present. Confabulation, in which the intrusion of errors in response to questions leads to fabrication of answers without the intention to deceive, is sometimes present spontaneously in the first weeks after Wernicke encephalopathy. Since it is most likely a compensatory mechanism, it usually lessens over time. Neuropsychological testing frequently demonstrates emotional changes and mild problems in executive function, which are indicative of frontal lobe involvement.

TREATMENT

Prophylactic treatment (i.e., >100 mg daily of thiamine replacement) of anyone at risk due to vomiting, starvation, bariatric surgery, and dialysis (see Table 384-1) can prevent Wernicke encephalopathy as well as beri-beri. In the acute setting, especially in intensive care units, all patients should receive replenishment with high-dose IV or IM thiamine (500 to 1000 mg daily for 3 to 5 days) prior to any glucose administration to circumvent any problems with swallowing or absorption. Treatment will lead rapidly, often within hours, to complete resolution of nystagmus and oculomotor paresis, followed by resolution of the ataxia and eventually of the mental status changes attributable to thiamine deficiency. Magnesium (Chapter 105) and sodium also must be replaced if deficient.

PROGNOSIS

The cognitive function in Korsakoff tends to be stable,[7] but many alcoholic patients may have residual ataxia and cognitive impairment, including memory dysfunction, owing to the toxic effects of alcohol itself. As a result, about 50% of treated patients die within 8 years. Because Korsakoff syndrome does not respond to thiamine replacement, prevention by timely recognition of Wernicke encephalopathy is essential. Untreated, Wernicke encephalopathy is fatal in 90% of cases, and the mortality rate can be as high as 20% even in treated patients.

COBALAMIN (VITAMIN B_{12}) DEFICIENCY

Cobalamin is involved in methionine pathways that regulate the formation of myelin during development and maintain myelin throughout life (Chapter 199).[8] Deficiency results in combined system disease (peripheral neuropathy and spinal cord degeneration) or subacute combined degeneration of the dorsal (sensory) and lateral (motor) tracts (i.e., myelopathy). The spinal cord tracts that are dysfunctional result in impaired position and vibratory sensation and spastic paraparesis. Impairment of cognitive function is not as closely correlated with B_{12} deficiency.

Cobalamin deficiency is rarely due to inadequate dietary intake (e.g., a vegan diet for several years), because it is stored in fat and found in many foods, although more in animal proteins than vegetables. Failure to absorb the vitamin results in its deficiency, especially in individuals over age 60 years (Chapter 150) because the prevalence of atrophic gastritis (Chapter 125) with lack of intrinsic factor and achlorhydria rises in older individuals. Long-term use of proton pump inhibitors can also cause the same lack of gastric acid required for B_{12} absorption. A more common cause in recent years is failure to maintain supplement use after bariatric surgery, with a higher risk after bypass (i.e., Roux-en-Y) than after restrictive surgery (i.e., sleeve gastrectomy or balloon placement). Reduced absorption can also occur with bacterial overgrowth, inflammatory bowel disease (Chapter 127), and rarely, tapeworm infestation (Chapter 315). Nitrous oxide ("laughing gas") toxicity, usually from illicit use rather than administration as an anaesthetic, can cause cobalamin deficiency by inactivating the cobalamin-dependent enzyme methionine synthase. Long-term treatment of diabetes with metformin can lower B_{12} levels. Low vitamin B_{12} levels have been associated with increased homocysteine levels, but a relationship to vascular disease or vascular dementia is not established.

CLINICAL MANIFESTATIONS

Demyelination of the dorsal columns causes proprioceptive loss that can result in sensory ataxia owing to loss of position sense in the feet. A positive Romberg sign (failure to maintain balance only after the eyes are closed) distinguishes sensory from cerebellar ataxia. A non–length-dependent axonal peripheral

neuropathy[9] causing numbness and tingling in the hands and feet is often present, but spinal cord disease is more prominent and less amenable to recovery. Motor nerve function eventually becomes impaired as well. The optic nerve is the most commonly involved cranial nerve, but vagal neuropathy also can occur. Signs of cerebral involvement include memory loss, personality changes, and occasionally hallucinations and psychosis. Although encephalopathy and dementia may be present, B_{12} deficiency may be a secondary phenomenon in a patient with another cause of memory impairment, or both conditions may coexist without a causative relationship. Neurologic abnormalities may precede or be present without anemia, although the anemia is severe in 20% of patients with vitamin B_{12} deficiency. Symptoms generally progress slowly, but they can appear rapidly after exposure to nitrous oxide anaesthesia in individuals who have preexisting subclinical cobalamin deficiency.

DIAGNOSIS

Serum vitamin B_{12} levels are usually low (<300 pg/mL) but can be normal in symptomatic patients. In such cases, serum levels of methylmalonic acid and homocysteine are useful ancillary tests because these levels are increased as a result of impaired cobalamin-dependent reactions. Pernicious anemia (Chapter 150), an autoimmune disease diagnosed by measuring intrinsic factor antibodies, is severe in about 20% of patients. However, both the hematocrit and mean corpuscular volume are sometimes normal because the hematologic effects of cobalamin deficiency can be partially masked by folate supplementation. Inactivated cobalamin from nitrous oxide exposure cannot be detected by most assays; despite the normal B_{12} level, methylmalonic acid levels are elevated.

Low cobalamin levels are sometimes present in normal people, especially the elderly, in which dementia, peripheral polyneuropathy, and myelopathy may be due to a myriad of unrelated causes. Therefore, a low cobalamin level may reflect poor nutrition or absorption rather than being the cause of these conditions. Causality is definitively confirmed by clinical improvement after cobalamin replacement, which usually begins only after several weeks and may continue for up to a year.

The myelopathy (Chapter 369) may be difficult to distinguish from other causes. However, a magnetic resonance image (MRI) showing an increased T2 signal in the posterior and lateral columns of the spinal cord and in periventricular white matter can help exclude other causes of myelopathy.

TREATMENT

Treatment begins by repleting low B_{12} levels with subcutaneous or IM injections of 1000 to 2000 μg of cobalamin daily for 1 week and then weekly for 1 month. After that time, oral supplementation continued indefinitely with 1000 μg daily of cyanocobalamin usually suffices in patients with achlorhydria, a history of bariatric surgery, pernicious anemia, or other causes of malabsorption.[A1] If no response in serum levels is seen with oral treatment, intramuscular monthly injections should be continued instead. Sublingual, transdermal patch, and nasal gel forms (500 μg weekly) have not been adequately studied. The anemia can be corrected by high-dose folate replacement, but the neurologic damage will progress unless vitamin B_{12} is administered.

PROGNOSIS

Neurologic symptoms, especially paresthesias, typically improve to some extent within 3 months of achieving adequate B_{12} serum levels. Numbness and areflexia often persist, especially if treatment is delayed. If there is no improvement whatsoever, causes other than vitamin B_{12} deficiency are likely, such as copper deficiency or human immunodeficiency virus (HIV)–associated myelopathy. Similarly, vitamin B_{12} supplementation does not affect cognitive performance in hyperhomocysteinemic elderly people without clinical signs of B_{12} deficiency.

FOLATE DEFICIENCY

Folate is an important coenzyme in the metabolism of nucleic and amino acids (Chapter 199). Maternal deficiency accounts for 50% of babies born with neural tube defects and may cause more subtle neurologic problems, including autism.[10] Inborn errors of folate metabolism cause seizures and intellectual disability. Other signs include psychomotor retardation, autism, dyskinesias, and irritability. In adults, neurologic symptoms of folate deficiency overlap with those of B_{12} deficiency and include peripheral neuropathy,[11] cognitive impairment, depression, and rarely, retrobulbar optic neuropathy. Folate deficiency also results in elevated levels of homocysteine, which is associated with an increased risk for ischemic heart disease and stroke, although replacement to correct homocysteine level does not prevent cardiovascular disease.[12] Patients with genetic folate deficiency due to lack of methylenetetrahydrofolate reductase, which converts ingested folate to the active metabolic cofactor, have an increased risk of intracerebral hemorrhage.

The supplementation of flour with folate has greatly reduced the risk of folate deficiency, and pregnant women are now generally prescribed supplemental folate. Women of childbearing age should be treated even before pregnancy if they have any conditions that predispose to folate deficiency, such as the use of antiepileptic or other medications that induce folate metabolism.

Folate deficiency also can lead to megaloblastic anemia (Chapter 150). Before correction of megaloblastic anemia with folate alone, vitamin B_{12} levels should be checked to avoid ongoing neurologic injury from unrecognized cobalamin deficiency.

TREATMENT AND PROGNOSIS

Folate deficiency is treated orally with 1 mg three times daily for 1 month, followed by 1 mg daily; improvement takes many months. Return of folate and homocysteine serum levels to normal has not shown benefit for preventing progressive cognitive impairment, for preventing stroke, or for reducing adverse vascular events except in patients with classic homocysteinemia (Chapter 193).

PYRIDOXINE (VITAMIN B_6) DEFICIENCY AND TOXICITY

Pyridoxine is a coenzyme in multiple reactions that involve gluconeogenesis, biosynthesis of neurotransmitters, and the metabolism of amino acids, nucleic acids, and lipids. Pyridoxine deficiency can be caused by genetic defects, such as defective antiquitin, that lead to increased utilization of pyridoxine. In adults, low serum pyridoxine levels are well tolerated, so symptomatic deficiency is rare, but it can occur in the setting of renal failure (Chapter 116) or dialysis (Chapter 117), cirrhosis (Chapter 139), or with medications such as isoniazid for antitubercular therapy (Chapter 299) or hydralazine for heart failure (Chapter 46) if patients do not receive concurrent supplementation. Deficiency is also seen with extreme malnutrition, especially diets consisting predominantly of white rice. Pyridoxine deficiency in pregnancy can be caused by hyperemesis gravidarum (Chapter 221).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pyridoxine Deficiency

Prolonged pyridoxine deficiency causes a painful peripheral axonal neuropathy that leads to weakness and sensory ataxia. Genetic defects can rarely present in adolescence or adulthood with neuropathy,[13] but adult pyridoxine deficiency is almost always acquired, not genetic. Some patients have skin thickening, seborrheic dermatitis, or glossitis, which can resemble pellagra.

Serum levels of the active form of pyridoxine, pyridoxal 5′-phosphate, and urine levels of the metabolite 4-pyridoxic acid are low. Ancillary tests include nerve conduction studies, which show significantly reduced amplitudes in sensory and motor action potentials with normal conduction velocity times, typical of an axonal neuropathy. In the setting of seizures, which is predominately a neonatal manifestation, electroencephalography shows a highly disorganized pattern with excessive slow frequency activity and abundant multifocal and generalized spikes, similar to hypsarrhythmia.

Pyridoxine Toxicity

Toxicity occurs due to excess pyridoxine intake (usually ≥200 mg daily). A competition between the inactive pyridoxine form and the active form of pyridoxal-5′-phosphate, which is a cofactor in a myriad of enzyme actions, can occur in patients who take large amounts of vitamin supplements (which require no prescription) or after accidental intravenous overdose (Table 384-2). In the United States, a 100 mg daily supplement is thought to be safe, despite controversial isolated reports of toxicity at lower doses. Toxicity is characterized by a ganglioneuropathy with purely sensory symptoms, including sensory loss, ataxia, areflexia, and prominent Romberg sign. Blood pyridoxine levels are typically more than 10 times the normal upper limit.

TREATMENT

Patients in whom symptoms of pyridoxine deficiency develop or who take pyridoxine antagonists should receive supplemental pyridoxine (50 to 100 mg daily). Children with pyridoxine-dependent epilepsy require immediate and lifelong supplementation with at least 100 mg of pyridoxine daily. Antisense therapy against the mutant gene is being tested.

For pyridoxine toxicity, simply stopping excess oral vitamin intake can improve damage. After intravenous exposure to toxic doses, however, ganglion cell death is mostly irreversible.

TABLE 384-2 VITAMIN AND MINERAL TOXICITIES

VITAMIN AND MINERAL TOXICITY	NEUROLOGIC SYMPTOMS	SUPPORTING TESTS	CAUSES	TREATMENT
Vitamin A	Idiopathic intracranial hypertension (pseudotumor cerebri): headaches, papilledema, blindness Embryotoxic effects	Lumbar puncture: elevated opening pressure (>250 mm H_2O); normal composition	• Excessive intake of vitamin A • Use of tretinoin for acne • Excessive consumption of liver from fish-eating animals (polar bear, seal, walrus) • Consumption of >10,000 IU/day during pregnancy	Stop the use
Vitamin B_3 (Niacin, Nicotinamide)	Flushing, headaches, lightheadedness			Stop the use
Vitamin B_6	Sensory ganglioneuropathy: sensory loss, areflexia, ataxia, Romberg sign, chorea, Lhermitte sign	Nerve conduction study: slow sensory conduction with normal motor velocities	Excess intake (>200 mg daily)	Stop the use
Vitamin E	Muscle weakness, intracranial hemorrhage	Level >23.3 μg/mL		
Vitamin D	Hypercalcemia Muscle and bone pain Confusion	Levels 150-2000 ng/mL with calcium >11 mg/dL	• Overcorrection of deficiencies • Accidental ingestion • Prolonged use of high doses	Stop the use
Copper	Psychiatric symptoms, dementia, chorea, tremor, dystonia	Kayser-Fleischer rings Low ceruloplasmin level		Chelation with penicillamine or zinc
Oxalyl diaminopropionic acid	Spastic paraparesis		Excess consumption of grass peas or chick peas	
Cassava tubers (Konzo)	Sensory ataxia, optic atrophy, sensorineural deafness (men), spasticity (women and children)		Potentiates cyanate and glucoside neurotoxicity	
Cycad toxins	Amyotrophic lateral sclerosis/parkinsonism in Guam			

Other B Vitamins

B_2 (Riboflavin)

Oxidation-reduction reactions require flavins, which are present in dairy products, meat, fish, vegetables, and fortified cereal and bread. Deficiencies are rare, but some inherited mitochondrial myopathies, mostly motor neuropathies and multisystem conditions caused by riboflavin electron transfer mitochondrial defects, can respond to supplementation with this vitamin.

B_3 (Niacin)

Pellagra is a symptom complex of photosensitive dermatitis, delirium or dementia, neuropathy, and diarrhea. It occurs in patients with malabsorption of niacin or in patients undergoing dialysis. The syndrome can be confused with alcohol withdrawal (delirium tremens) or psychosis. Pellagra is also seen in Hartnup syndrome, a recessively inherited failure to transport tryptophan, which is converted to niacin. In utero genetic deficiencies cause malformations of many organ systems, but it is often difficult to isolate the effects of niacin from other B vitamins.

B5 (Pantothenic Acid)

Deficiency of vitamin B_5 is rare, and disease associated with it is hard to prove, because it is often accompanied by deficiencies of other B vitamins. Also this vitamin is found in many different foods and is produced by colonic bacteria. The neurologic syndrome associated with B_5 deficiency is presumed to be a small-fiber neuropathy with dysesthesias and paresthesias that result in "burning feet." Treatment is with B complex vitamins. Treatment with gabapentin (Table 26-5) may help relieve neuropathic symptoms.

B_7 (Biotin)

Biotin (B_7) deficiency is caused by lack of protein in the diet, accidentally failing to add it to total parenteral nutrition, and an autosomal recessive disorder affecting biotinidase, which prevents biotin from being removed from proteins and recycled, so as to be accessible for metabolic use. Genetic causes result in developmental delay, seizures or myoclonus, ataxia, and deafness if supplementation is not begun in the newborn period. Biotinidase deficiency causes a combination of optic atrophy and spinal cord pathology that clinically resembles neuromyelitis optica (Chapter 392). Dietary deficiencies lead to lethargy, myalgias, and paresthesias, along with rash. Treatment is with B complex vitamins. Gabapentin (Table 26-5) may help with symptoms.

DEFICIENCY OF FAT-SOLUBLE VITAMINS

VITAMIN E (TOCOPHEROL) DEFICIENCY

Although vitamin E is composed of several tocopherols, it is the α form, which is found in plants such as leafy vegetables and vegetable oils, that is biologically active in humans.[14] Because it is so widely available, deficiency in adults (who require 15 mg/day) is almost never due to inadequate dietary consumption (malnutrition). Rather, vitamin E deficiency is the result of prolonged malabsorption of lipids in the setting of biliary and pancreatic disease (Chapters 141 and 130), cystic fibrosis (Chapter 77), celiac disease (Chapter 126), Crohn disease (Chapter 127), extensive small bowel resection, and blind loop syndrome (Chapter 126). In inherited forms, decreased availability of vitamin E is caused by faulty intracellular transport owing to structural defects in the α-tocopherol transfer protein, which is produced by a gene on chromosome 8q12.3, whose product binds the vitamin to protein, or to decreased absorption of lipids (hypolipoproteinemia and abetalipoproteinemia).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neurologic manifestations of vitamin E deficiency include a spinocerebellar syndrome with ataxia of gait or limbs (dysmetria)[15]; abnormal eye movements (nystagmus or dysconjugate gaze); loss of vibration and position senses (sometimes causing sensory ataxia or pseudoathetosis); distal sensory neuropathy with hyporeflexia; and, rarely, cognitive dysfunction, myopathy, or blindness owing to retinopathy. A normal blood vitamin E level is considered to be 11 to 37 μM/L in adults, but serum levels of vitamin E can vary with the serum lipid level. Especially in patients with extreme hyperlipidemia, such as cholestasis, the ratio of vitamin E to cholesterol will be more reliable than the absolute vitamin E level.

Although generally not toxic, excessive intake of vitamin E causes bleeding, including hemorrhagic infarcts, in adults, probably from its effects on platelets. Myalgia, mild proximal weakness, and elevated serum creatine kinase levels can also occur. During pregnancy, high doses of vitamin E can interfere with oxidation in the fetus and cause growth retardation.

TREATMENT

Treatment depends on the cause of the deficiency. Malabsorption syndromes require 1000 to 2000 mg daily (where 1 mg is equivalent to 1.49 IU) for infants and 100 mg/kg/day (10 to 20 g) for adults, with 300 mg daily considered adequate supplementation after bariatric surgery. Genetic causes can be treated with 5 to 10 g/day.

VITAMIN D (CALCIFEROL) DEFICIENCY

Vitamin D deficiency is often diagnosed in asymptomatic adults because of frequent screening, despite the U.S. Preventive Services Task Force's recommendations against screening (Chapter 199).[16] Although there is no absolute

cutoff, serum levels of 25(OH) D below 30 nmol/L can cause parathyroid dysfunction with subsequent dysregulation of calcium and serum electrolytes (Chapter 227). Deficiency results from impaired skin synthesis owing to inadequate exposure to sunlight, dietary insufficiency, intestinal malabsorption; or sequestration of the vitamin as it is stored in fat cells of obese patients. The average multivitamin contains 400 IU of combined D_2 (ergocalciferol) and D_3 (cholecalciferol), whereas 20 minutes of full-body summer sun exposure provides 10,000 IU of D_3, the form used in the body.

CLINICAL MANIFESTATIONS

Vitamin D deficiency causes rickets in children and osteomalacia (Chapter 226) in adults. Bone remodelling and degenerative changes in vertebral end plates near intervertebral discs may lead to vertebral collapse and resulting compression of the spinal cord or nerve roots (Chapter 369). Abrupt extreme lack of vitamin D causes hypocalcemia with secondary hyperparathyroidism (Chapter 227). Hypocalcemia, in turn, can cause tetany, encephalopathy, and generalized seizures. Deficiency also causes a proximal myopathy (owing to impaired calcium influx or actin and troponin production), which is worse in the legs and pelvic girdle than the arms and which can lead to peculiar patterns of gait as a result of weakness and fear of falling. This myopathy is associated with sleep disorders and fibromyalgia without weakness. Vitamin D deficiency is also associated with an increased incidence of Alzheimer and all-cause dementia.[17] Low levels of vitamin D also may adversely affect postural stability in Parkinson patients.

Vitamin D plays a role in immune modulation of regulatory T cells, which may explain the relationship of vitamin D deficiency to an earlier onset, higher prevalence, higher relapse rate, and more severe manifestations of multiple sclerosis (Chapter 380). Other autoimmune diseases, such as narcolepsy (Chapter 374), also are more common in patients with low levels of vitamin D.

DIAGNOSIS

Normal serum levels of 25(OH)D are 20 to 40 ng/mL. Measurement of 1.25 (OH)D is not useful.

TREATMENT

Individuals whose dietary absorption is normal require 400 to 600 IU (10 to 15 µg) of vitamin D_3 daily, but persons with malabsorption may need more than twice that amount. Supplementary doses depend on the degree of deficiency, with high doses (50,000 units, 1.25 mg) of ergocalciferol (D_2) given weekly for no more than 8 weeks to patients whose 25-OH calciferol level is very low (<20 ng/mL), followed by daily 400 to 800 IU of cholecalciferol (D_3). In patients with malabsorption, 1000 IU should be given daily, indefinitely. Serum levels should be monitored after reaching at least 20 ng/mL.

Supplementation of vitamin D in patients with normal 25-OH D levels is ineffective and may lead to fatigue and weakness from toxicity (see Table 384-2). Toxicity (serum levels of 150 to 1220 ng/mL) is extremely rare and generally iatrogenic because of overcorrection, accidental injection, or prolonged use of high-dose supplements. However, excess absorption of vitamin D is seen in sarcoidosis (Chapter 83) and other granulomatous conditions. The most dangerous symptom is hypercalcemia. Like deficiency states, vitamin D toxicity causes muscle and bone pain (Chapter 227) or mental confusion related to hypercalcemia. Very high doses also have been associated with an increased risk of falls.

VITAMIN A DEFICIENCY

Vitamin A is required to bind opsin to produce the retinal transmitter rhodopsin. It also plays a role in endothelial stability, especially in bone and smooth muscle. Vitamin A is found in animal products (retinol, retinoids) or as a provitamin in colorful plants such as carrots (beta-carotenoid). In adults, the absence of vitamin A impairs vision in conditions of low light ("night blindness"). In abetalipoproteinemia, in which vitamin E is also lacking, complete blindness may occur (Chapter 190). The ability to taste is also impaired, and hyperkeratinization of skin and cornea can occur.

Malabsorption must be very prolonged to produce vitamin A deficiency because this fat-soluble vitamin has large body stores. Repletion in patients with corneal changes requires intramuscular doses of 50 to 100,000 units for up to 2 weeks.

Vitamin A toxicity is rare but can occur in patients who use isotretinoin for acne or have excessive dietary intake owing to the consumption of liver (especially from fish-eating mammals such as polar bear, seal, and walrus). Vitamin A in large amounts can cause idiopathic intracranial hypertension (Chapters 175 and 367) with headache and papilledema that leads to diminished vision or even blindness in severe cases. Excess vitamin A is also highly teratogenic (Table 384-2).

VITAMIN K DEFICIENCY

Vitamin K deficiency, a rare consequence of malabsorption, also can be seen in patients taking high doses of vitamin A or E. It is most often seen in patients who have compromised storage or synthesis in the liver or who are taking the antagonist warfarin (Chapter 199). Adequate intake is 90 µg daily for adult women and 120 µg daily for adult men. Vitamin K deficiency causes excessive bleeding and increases the risk of intracerebral hemorrhage. Hemorrhagic disease of the newborn (now known as vitamin K deficiency bleeding) can occur in offspring of mothers who take hepatic enzyme-inducing anticonvulsants (such as phenytoin) that increase vitamin K metabolism or any broad-spectrum antibiotics that kill the gut bacteria that are required to make vitamin K. This outcome is better prevented by routinely giving all newborns an injection of vitamin K rather than by maternal supplementation using 5 mg daily for the last month of pregnancy. Because vitamin K levels are difficult to obtain, functional testing of clotting with the international normalized ratio is typically used to guide replacement dose adjustments. Toxicity is not reported.

DEFICIENCY OF MISCELLANEOUS ELEMENTS AND NUTRIENTS

COPPER DEFICIENCY

Acquired copper deficiency (Chapter 199) is rare and can be difficult to recognize. It occurs most often in premature or malnourished infants and in patients with very prolonged malabsorption owing to celiac disease (Chapter 126), cystic fibrosis (Chapter 77), Crohn disease (Chapter 127), or intestinal blind loops after surgery (e.g., a Whipple procedure for pancreatic or other malignancy, or bypass surgery for weight loss). It can also occur in patients with nephrotic syndrome (Chapter 107) and intestinal bacterial overgrowth (Chapter 126). Copper deficiency is also a well-recognized consequence of excessive intake of zinc (from denture paste, wound cream, eating pennies, or herbal therapy for colds) or as a consequence of parenteral overload during hemodialysis (Chapter 117), which competitively upregulates copper loss in the intestine.

The most common neurologic complication of copper deficiency is a myelopathy that is clinically very similar to that of cobalamin deficiency. The most prominent features are spastic paraparesis and sensory ataxia. An insidious peripheral polyneuropathy, initially sensory and eventually motor, of the axonal type is usually present as well. Optic neuropathy with hallucinations or visual loss, wrist drop, and foot drop have also been reported. Copper levels, including excreted urinary copper, should be measured in patients who have symptoms suspicious for vitamin B_{12} deficiency but have normal vitamin B_{12} levels or who fail to respond to cyanocobalamin replacement. Treatment consists of oral copper supplementation, 8 mg/day tapering by 2 mg weekly over 3 weeks, followed by maintenance of 2 mg/day for life. Zinc overexposure should be sought and stopped. A ratio of 8 to 15 mg of zinc to 1 mg of copper should be supplied after bariatric surgery.

Menkes disease, an X-linked recessive copper deficiency caused by mutations in the *ATP7A* gene needed for absorption, is characterized by severe intellectual disability and kinky hair. The diagnosis is made by finding low serum copper levels or changes in the ratio of dopamine to norepinephrine. Large doses of copper histidine (250 mg twice daily until age 1, then daily until age 3) must be delivered subcutaneously, but improvement is variable. Patients survive to adulthood only if persistent copper injections are begun in the neonatal period.

Toxicity from copper is indirectly caused by Wilson disease (Chapter 195, Table 384-2), which is an autosomal recessive disorder caused by a mutation in the *ATP7B* gene that encodes ceruloplasmin, a copper-transporting protein (Chapter 195). Psychiatric features such as personality change, disinhibition, depression, and psychosis sometimes overshadow neurologic manifestations such as dementia, dysarthria, chorea, tremor, and dystonia. Deposition of copper in the eye's Descemet membrane causes the characteristic Kayser-Fleischer ring (Fig. 195-2), which is seen in the iris in over 95% of patients. Serum ceruloplasmin levels are low. Accumulation of copper in the liver leads to chronic liver failure. Wilson disease is treated by copper chelation with penicillamine or zinc (Chapter 195) along with minimization of dietary intake.

OTHER NUTRITIONAL DISORDERS

Iodine deficiency leads to hypothyroidism (Chapter 207), which causes varying degrees of congenital iodine deficiency syndrome (formerly cretinism) in the

offspring of mothers with insufficient thyroid hormone. Selenium deficiency leads to skeletal and cardiac muscle dysfunction; supplementation with at least 100 μg daily after bariatric surgery is necessary.

Overreliance on one hardy food source (e.g., grass peas, chick peas) may lead to spastic paraparesis from lathyrism owing to oxalyl diaminopropionic acid, which is a neurotoxic glutamate agonist. In older Nigerian men who consume excess cassava tubers (konzo) or tapioca (which contains the cyanide-like product cyanogenic glycoside), neurotoxicity (Chapter 96) symptoms include sensory neuropathy, ataxia, optic atrophy, and sensorineural deafness. In contrast, women and children develop spasticity, presumably from the same toxin. Amyotrophic lateral sclerosis (Chapter 387) and Parkinson-dementia (Chapter 378) complex in Guam are probably caused by cycad toxins in flour (see Table 384-2). Occasional epidemics that combine toxins such as alcohol or smoking with malnutrition and respond clinically to vitamin B supplementation are presumed to reflect deficiencies of various nutrients. Examples are Strachan Jamaican neuropathy and Cuban tobacco-alcohol amblyopia with optic neuropathy.

ALCOHOL-RELATED DISORDERS

Alcohol (Chapter 364) is responsible for a wide spectrum of neurologic disorders.[18] At one extreme, it can cause irreversible dementia, cerebellar degeneration, optic neuropathy, and peripheral polyneuropathy. Syndromes are "dose dependent" in the sense that greater durations and amounts of alcohol use produce more serious complications.[19] Binge drinking, combined with B-vitamin deficiencies and electrolyte derangements, also contribute to neurologic disease. Intoxication and withdrawal states may obscure other serious conditions such as osmotic demyelination syndromes and Wernicke encephalopathy, thereby delaying treatment.

Acute intoxication can range from mild euphoria to vestibular and cerebellar dysfunction to coma and death. Intoxication may also affect judgment and coordination, thereby contributing to subsequent vehicular accidents, falls, traumatic brain injury, violence, and other unsafe behaviors. After chronic excessive alcohol intake, cessation or lowering of alcohol consumption can lead to withdrawal, which presents with overexcitation syndromes such as seizures, tremors, and autonomic overload. Untreated withdrawal can lead to fatal delirium tremens. Sleep homeostasis is disrupted by binge drinking,[20] thereby making rebound of rapid eye movement (REM) sleep a possible contributor to the hallucinations of alcohol withdrawal.

Alcohol-induced liver toxicity results in hepatic encephalopathy (Chapter 139) and, rarely, acquired hepatocerebral (lenticular) degeneration. Coagulopathy caused by liver disease or suppressed platelet production and function raises the risk for subdural or intracranial hematoma (Chapter 368). Fetal alcohol syndrome reflects the vulnerability of the developing nervous system to the toxic effects of alcohol, especially during the first two trimesters.[21]

Signs of intoxication correlate with blood alcohol levels: 50 mg/dL for personality changes and disinhibition of behavior; 150 mg/dL for ataxia, vestibular dysfunction, and nystagmus; 300 mg/dL for stupor; 400 mg/dL for coma; and 500 mg/dL for respiratory depression or apnea. Owing to slower rates of metabolism, women require fewer drinks than men to reach equivalent serum levels. However, the effects of alcohol intake vary greatly depending on the chronicity of intake (tolerance) and the rate at which high levels develop. Intoxication alone should never be assumed to be the sole cause of a depressed mental state because people with alcohol use disorder are at increased risk for other treatable causes of coma (Table 373-2), such as repeated seizures and herniation from hemorrhage (Fig. 384-2).

SPECIFIC CLINICAL ALCOHOL-RELATED SYNDROMES

Seizures and Status Epilepticus

Seizures and status epilepticus (Chapter 372) can be a direct consequence of intoxication or of withdrawal, or they can be a result of associated electrolyte derangements, including hyponatremia (Chapter 102), hypomagnesemia (Chapter 105), and hypoglycemia (Chapter 211).[22] Patients with preexisting epilepsy (Chapter 372), possibly from epileptogenic foci owing to previous head trauma (Chapter 368) or stroke (Chapter 376), have an increased risk that alcohol will lower their seizure threshold, interfere with their adherence to anti-seizure medication, or disrupt their sleep. Patients with prior withdrawal-related seizures are at increased risk for recurrence. However, imaging by CT or MRI is always indicated to exclude other causes of seizures.

TREATMENT AND PROGNOSIS

Alcohol-related seizures, which may be focal or generalized, require treatment with antiseizure medication (Table 372-7). Withdrawal seizures, which precede the autonomic excitation of delirium tremens by several hours, warrant observation and benzodiazepine therapy at the time of the seizure (e.g., lorazepam 2 mg intravenously) followed by a tapering dose to suppress withdrawal symptoms (e.g., oxazepam, usually starting at 30 mg every 4 hours and then reducing the dose as the patient's response dictates) for about 3 days.

Consideration should be given to non-GABAergic seizure medications, such as levetiracetam or phenytoin (Table 372-7), instead of medications with dual purposes, such as barbiturates or gabapentin.

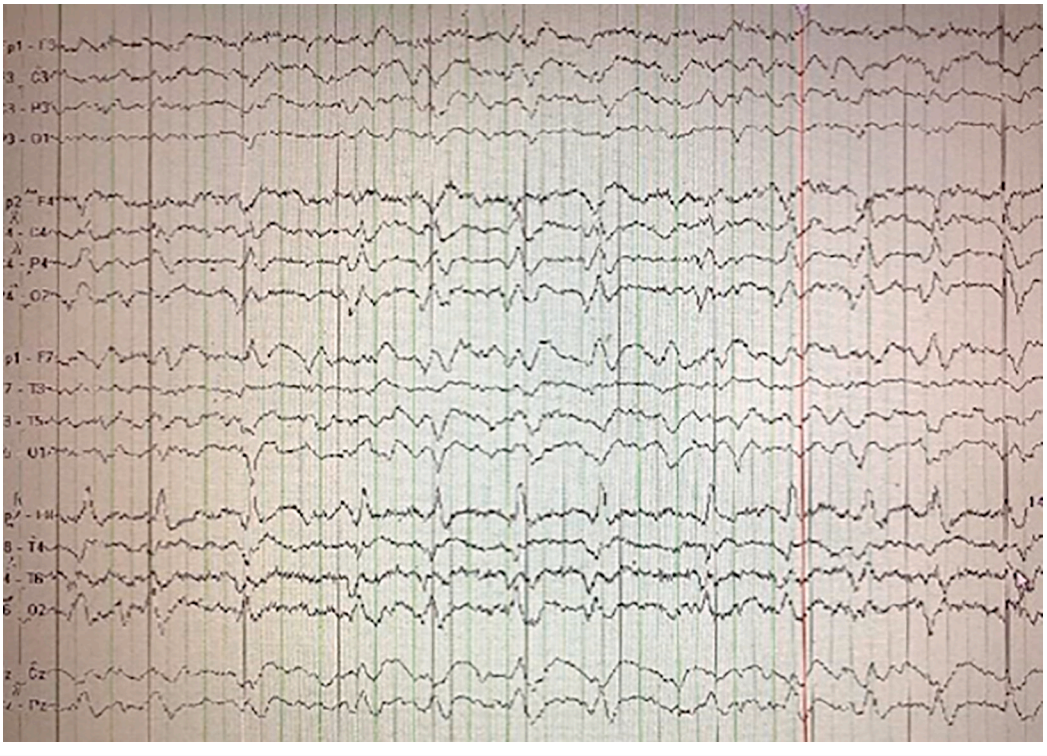

FIGURE 384-2. Hepatic encephalopathy. Electroencephalography of patient with alcohol use disorder and hepatic encephalopathy demonstrating triphasic waves and background slowing.

Hepatic Encephalopathy

Hepatic encephalopathy is most often seen in patients with end-stage alcoholic cirrhosis (Chapter 139). The characteristic manifestations are irritability alternating with depressed mental status, somnolence, seizures, tremor, and asterixis. Protein loads, including bleeding from esophageal varices or gastritis, can trigger decompensation. Encephalopathy also can be iatrogenic in patients treated for alcohol withdrawal with protocol-driven benzodiazepines instead of dosing in response to symptoms of withdrawal.

DIAGNOSIS AND TREATMENT

Electroencephalography demonstrates slowing and triphasic waves (Fig. 384-3). Although temporary reversal of encephalopathy with flumazenil (2 mg IV) can confirm the diagnosis, treatment focuses on trying to reduce the serum ammonia level, usually with lactulose (15 to 30 mL orally twice daily) or polyethylene glycol 3350-electrolyte solution (4 L orally or by nasogastric tube over 4 hours; see Chapter 139) to speed gastrointestinal transit time. Nonabsorbable antibiotics such as rifaximin (550 mg twice daily), neomycin (500 mg to 1 g three times daily), or metronidazole (250 mg two to four times daily) can be used chronically. Closure of spontaneous portosystemic shunts by embolization may be effective for reducing intractable encephalopathy in some patients.

Dementia and Other Encephalopathies

Headache (hangover) is probably due to low CSF pressure found in dehydrated binge drinkers.[23] Wernicke encephalopathy and Korsakoff syndrome (see earlier) are seen in alcoholic patients, especially binge drinkers, owing to thiamine deficiency. Dementia, not the memory disorder of Korsakoff syndrome, can develop even when nutrition is well maintained because of alcohol's direct and irreversible neurotoxic effects owing to glutamate excitotoxicity and oxidative stress. The absolute amounts of alcohol necessary to produce dementia are unclear and vary among patients. In younger patients with dementia, 10 to 25% of cases may be attributable to alcohol. Alcohol may also exacerbate Alzheimer disease.

Frontal lobe dysfunction results in deficits of executive function (planning, abstract reasoning) rather than the amnesia that is prominent in Korsakoff syndrome. Additional damage from head injury, status epilepticus, and cerebrovascular disease can contribute to cognitive dysfunction.

The appearance of cerebral atrophy is further evidence of alcohol's deleterious effect on cortical and white matter fibers. Abstinence is advised to limit degeneration. Standard dementia therapies are not very effective.

Cerebellar Degeneration

Cerebellar degeneration and ataxia result from alcohol-induced loss of Purkinje cells, mainly in the anterior superior part of the cerebellar vermis; the cerebellar hemispheres are less affected. As a result, the clinical picture is one of mainly truncal and gait ataxia, with a wide-based unsteady gait and inability to walk tandem. The arms are usually spared, with no intention tremor; nystagmus and dysarthria are rare when the patient is not intoxicated. Findings are exacerbated by concurrent thiamine deficiency. Alcohol may activate antibodies against Purkinje cells in individuals with gluten intolerance.

No treatment is available other than adaptive physical therapy. Prognosis for recovery of function is poor.

Alcoholic Neuropathies

Optic Neuropathy

Optic neuropathy, which occurs with severe chronic alcohol abuse, is manifested as progressive painless visual loss and sometimes visual hallucinations as a result of damage to the optic nerve fibers. The macular region is most affected. The prognosis is poor.

Alcoholic Peripheral Neuropathy

Peripheral neuropathy (Chapter 388) ("alcoholic neuropathy") is the most common neurologic complication of chronic alcoholism. It is an axonal sensorimotor neuropathy that causes dysfunction of small nerve fibers, thereby producing painful sensory symptoms such as burning and paresthesias of the feet. Numbness develops in a stocking-glove distribution, with loss of ankle reflexes. Mild distal weakness eventually occurs in some patients. Involvement of the autonomic nervous system frequently causes impotence as well as urinary or bowel complaints. Neurophysiologic testing reveals primarily axonal patterns. Concurrent thiamine deficiency should be excluded or treated. Although supplements of thiamine and pyridoxine may lead to some improvement, especially in the painful paresthesias, complete resolution is rare. If abstinence from alcohol is not also achieved, the symptoms persist, thereby implying that a direct toxic effect of alcohol is likely.

Compressive Neuropathies

Compressive neuropathies, especially of the radial nerve ("Saturday night palsy") or fibular nerve, can result after prolonged pressure on a nerve while the patient is obtunded from heavy alcohol consumption. Recovery takes many weeks but is generally complete.

Alcoholic Myopathy

Alcoholic myopathy (Chapter 389) occurs in binge drinkers, in whom severe muscle injury with rhabdomyolysis (Chapter 99) can develop, especially in the setting of fasting and prolonged absence of movement. Myoglobinuria can result in kidney damage. Heavy alcohol consumption is also associated with cardiomyopathy (Chapter 47), which can lead to arrhythmias even in the absence of hypokalemia. Chronic steady (not binge) alcohol use causes a symmetrical proximal weakness (Chapter 389) and muscle loss that is not

usually severe enough to prevent walking or standing. It can be detected in up to 50% of heavy users and is more prevalent in women.

Fetal Alcohol Syndrome

Fetal alcohol syndrome is recognized at birth in infants whose mothers consumed significant amounts of alcohol in the early stages of pregnancy.[24] The quantity required to place a fetus at risk has not been definitively determined, so abstinence is generally recommended throughout pregnancy. Rates as high as 55 per 1000 births have been described.

The characteristic findings are growth retardation, microcephaly, hypotonia, skeletal and cardiac anomalies, and characteristic facial features (micrognathia, small palpebral fissures). Exposure of the developing brain to alcohol can also lead to subtle or severe neurocognitive defects and attention-deficit disorder, which may not be detected until later in childhood. Although malnutrition and excess alcohol have synergistic deleterious effects, the teratogenic effects of alcohol are not prevented by adequate amounts of thiamine, folate, and other vitamins.

OSMOTIC DEMYELINATION

Osmotic demyelination syndrome (formerly called central pontine myelinolysis)[25] most commonly involves the pons, with or without the basal ganglia and thalamus, and sometimes also involves the corpus callosum, where it is also known as Marchiafava-Bignami syndrome. Chronic hyponatremia (Chapter 102) with cerebral edema leads to depletion of osmoles in the brain areas where gray and white matter intermingle. Abrupt correction of the hyponatremia precipitates central dehydration; separation of axons from their surrounding myelin and apoptosis of oligodendrocytes lead to noninflammatory demyelination. Beer drinkers are at increased risk due to the antidiuretic hormone effect of beer.

Signs and symptoms include dysarthria and dysphagia, with abnormal eye movements (Video 384-3) and ataxia (pons), delirium or coma (thalami), and neuropsychiatric syndromes reflecting "split brain" disconnection of hemispheres (corpus callosum). Symptoms also can occur during recovery from Wernicke encephalopathy, thereby suggesting contributions from thiamine deficiency, malnutrition, and alcoholism. CT is easier to obtain in very ill patients (Fig. 384-3), but MRI can identify milder cases in which recovery can occur.

385 DEVELOPMENTAL AND NEUROCUTANEOUS DISORDERS

E. STEVE ROACH

The understanding of many neurodevelopmental disorders has improved dramatically because of high-resolution neuroimaging, which can detect structural defects that previously went unrecognized, genetic testing, and a better grasp of molecular mechanisms. As a result, targeted treatments are now available for some conditions.

NEURAL TUBE DEFECTS

The worldwide incidence of neural tube defects is about 1 to 10 per 1000 live births. In the United States, neural tube defects occur in about 3500 births per year, with anencephaly and spina bifida being the two most common forms.

Neural tube defects are developmental anomalies resulting from failure of the anterior and posterior neuropore to close during gestation. Depending upon the embryologic stage at which the neuropore closure is disrupted, neural tube defects can manifest as anencephaly, encephalocele, and myelomeningocele with Chiari II malformation. Both genetic and environmental factors may play a role in neural tube defects. Although these lesions occur with increased frequency with chromosomal anomalies, single gene mutations are uncommonly associated with neural tube defects. In utero exposure to medications such as valproic acid is associated with neural tube defects. Folic acid deficiency also is associated with neural tube defects, and folate supplementation (6 mg/day) during pregnancy can reduce the risk of a neural tube defect by about 50 to 60%[1] (Chapter 221).

SPINAL MALFORMATIONS

Developmental anomalies of the vertebral bodies are common and cause pain and neurologic symptoms when they result in scoliosis (Chapter 86) or accelerated degenerative changes of the spine. Neurologic disability is likely when spine anomalies compress neural structures or alter the flow of cerebrospinal fluid.

SPINA BIFIDA

Spina bifida describes a spectrum of congenital defects, ranging from isolated, usually asymptomatic, bony defects of vertebral arch closure (spina bifida occulta) to a myelomeningocele, which is characterized by herniation of the spinal cord and meninges through a defect of the posterior spine. A myelocele is an open midline lesion with exposed neural elements that are flush with the adjacent skin (Fig. 385-1). The uncommon meningocele is characterized by herniation of leptomeninges and cerebrospinal fluid through a spinal defect without nerve tissue involvement.[2] Myeloceles and myelomeningoceles are visible at birth as midline back lesions.

EPIDEMIOLOGY

The incidence of myelomeningocele and other neural tube defects has been decreasing in recent years, probably because of folate supplementation in bread and the routine prescription of perinatal folic acid. It occurs at a rate of 1 per 1000 births worldwide. In the United States, the incidence is about 0.6 per 1000 births. Females are affected slightly more often than males.

ABSTRACT

Our understanding of many neurodevelopmental disorders has improved owing to high-resolution imaging procedures and more precise genetic techniques. This chapter summarizes selected congenital disorders of the brain and spinal cord, such as neural tube defects, Chiari malformation, syringomyelia, holoprosencephaly, and agenesis of the corpus callosum. Also included are genetic and developmental disorders such as autism, Down syndrome, fragile X syndrome, and Rett syndrome. Several neurocutaneous disorders presented in detail include tuberous sclerosis complex, neurofibromatosis types 1 and 2, Sturge-Weber syndrome, and von Hippel-Lindau disease. Disease-modifying therapy is available for tuberous sclerosis, neurofibromatosis type 1, and possibly fragile X and Rett syndromes. For other conditions, improved identification and treatment of disease complications has greatly improved longevity and quality of life.

KEYWORDS

spina bifida
anencephaly
Down syndrome
tuberous sclerosis
neurofibromatosis
Sturge-Weber syndrome
autism

PATHOBIOLOGY

A myelocele results from failure of posterior neuropore closure by day 26 of embryogenesis. Chromosomal deletions, duplications, and trisomy can lead to neural tube defects, but single gene mutations are uncommon. Low serum folate levels promote neural tube defects, and vitamin A deficiency may play a role in some individuals. The use of valproic acid during pregnancy increases the likelihood of neural tube defects.

CLINICAL MANIFESTATIONS

The manifestations of spina bifida depend primarily on the location of the lesion on the spinal axis and the extent of spinal cord involvement. Spina bifida occulta is typically asymptomatic and often discovered as an incidental finding on imaging studies. Myelomeningoceles and myeloceles can affect any portion of the spinal column, but the lumbosacral region is by far the most common site. Lumbosacral lesions typically cause less devastating dysfunction than lesions in the thoracic or cervical region. Loss of sensation and motor weakness typically occur below the level of spinal cord lesion, thereby contributing to the development of ulcers or other injuries. Bowel and bladder control are generally impaired regardless of the affected level. Frequent urinary tract infections can promote renal failure.

Myelomeningoceles are often associated with other conditions, such as a tethered cord, a Chiari II malformation, or agenesis of the corpus callosum. Epilepsy is common, particularly among individuals with an associated brain malformation or hydrocephalus. Kyphosis, clubfoot, and extremity contractures are frequent complications. Although the mechanism is incompletely understood, latex allergy is common, and its frequency tends to increase with age.

DIAGNOSIS

Abnormalities are often detected on prenatal ultrasound studies. In addition to prenatal ultrasound studies, prenatal detection of myelomeningoceles is aided by elevated concentrations of alpha-fetoprotein and acetylcholinesterase; the latter normally occurs in the cerebrospinal fluid but not in amniotic fluid. Ultrasound and magnetic resonance imaging can help define the extent of the abnormalities.

TREATMENT

A baby with an open neural tube defect should begin antibiotics after birth and undergo surgical closure within three days. Individuals with hydrocephalus usually require a ventriculoperitoneal shunt. Prenatal closure of the spinal lesion may reduce the incidence of hydrocephalus. Myelomeningocele is a static lesion, so any deterioration in neurologic function could signal worsening hydrocephalus, a tethered cord, or a syrinx. Proper attention to skin care and bladder training may limit the number of pressure ulcers and urinary tract infections, and neuropsychologic care can help patients deal with the disease.[3]

CHIARI MALFORMATION

A Chiari malformation denotes the downward displacement of structures in the posterior fossa through the foramen magnum. A Chiari I malformation, which is characterized by the displacement of the cerebellar tonsils more than 5 mm below the foramen magnum, occurs in about 1% of patients who undergo cranial magnetic resonance imaging (MRI).[4] A Chiari II malformation typically occurs in association with a myelomeningocele and hydrocephalus. It is characterized by downward displacement of cerebellar vermis, tonsils, fourth ventricle, and medulla, with "beaking" of the midbrain, in which the posterior midbrain appears elongated in sagittal images.

Most Chiari I malformations remain asymptomatic, although some individuals with more severe displacement develop occipital headaches, particularly with straining, or lower cranial neuropathies that manifest as tongue weakness, vocal cord paralysis, or recurrent aspiration. Since Chiari II malformations typically occur in conjunction with a myelomeningocele (see Spina Bifida) and hydrocephalus, affected individuals often experience seizures, cognitive delay, paraplegia, and sphincter dysfunction. Diagnosis is confirmed by magnetic resonance imaging (MRI) without contrast showing displacement of the cerebellar tonsils more than 5 mm below the foramen magnum (Fig. 385-2). Given the high frequency of asymptomatic Chiari I malformations, it can be difficult to determine whether the malformation is responsible for the patient's symptoms, particularly when the tonsillar displacement is not severe.

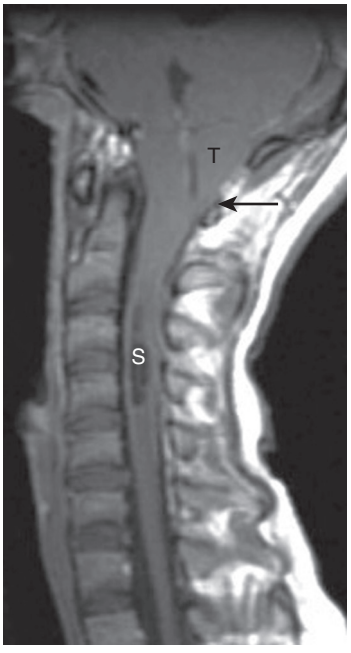

FIGURE 385-2. Chiari I malformation. A sagittal magnetic resonance image shows low, pointed cerebellar tonsils (i.e., Chiari I malformation, T) that extend to the level of C1 *(arrow)* and a dilated central canal of the spinal cord (i.e., syringohydromyelia [S]). (From Barkovich AJ, Kuzniecky RI. Congenital, developmental, and neurocutaneous disorders. In Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine*. 23rd ed. Philadelphia: Saunders Elsevier; 2008:2790.)

TREATMENT

Patients with a symptomatic Chiari I malformation may require a posterior fossa decompression. Surgery is not usually necessary for mildly symptomatic or asymptomatic patients, and expert consultation is required to assess the potential benefit of decompressive surgery.[5] Individuals with a Chiari II lesion typically require surgical repair of the associated myelomeningocele and shunting of the hydrocephalus. Bladder dysfunction may necessitate intermittent catheterization and treatment of urinary tract infections (Chapter 263) and genitourinary reflux. Prognosis in Chiari II patients depends greatly on the severity of the brain abnormalities and myelomeningocele.

TETHERED SPINAL CORD

A tethered spinal cord results from abnormal fixation of the filum terminale to the lower spinal structures. Tethering can represent a developmental anomaly or occur in association with a myelomeningocele, intraspinal tumor, or infection. Common associated spinal anomalies include diastematomyelia (split cord), spinal lipomas, dermal sinuses, and fibrolipomas of the filum terminale. Progressive cord dysfunction can occur when repeated flexion and extension of the spine results in stretching of the tethered cord.

Symptoms can occur in either children or adults. Clinical manifestations vary with the patient's age and whether there is progressive dysfunction. Cutaneous findings can include a lumbar cutaneous lipoma, skin dimple, dermal sinus, or tuft of hair.[6] Associated orthopedic abnormalities include scoliosis and leg length discrepancy. Urologic manifestations include poor bladder control, loss of previously attained urinary continence, and recurrent urinary tract infections. Infants may have diminished spontaneous leg movements, whereas older children exhibit delayed walking, an abnormal gait, and poor bladder control. Adolescents and adults may experience difficulty walking, sensory loss, and back and leg pain. Sexual dysfunction and urinary incontinence are common. Many individuals with a tethered cord syndrome have a latex allergy, possibly due to recurrent latex exposures during procedures. The diagnosis is confirmed by an MRI showing a conus medullaris below the bottom of the L-2 vertebral border or thickened or fat-containing filum terminale.

TREATMENT

For symptomatic patients, surgical release of the tethered cord is recommended. For asymptomatic individuals, the value of surgery is uncertain, in part because the cord often retethers following surgery.

SYRINGOMYELIA

Syringomyelia is a cystic cavitation of the central portion of the spinal cord, whereas hydromyelia results from dilatation of the central spinal canal. Both lesions are typically located in the cervical cord but may extend into the medullary region (syringobulbia) or into the lower cord segments. Syringomyelia may develop in association with Chiari malformations (see Fig. 385-2), trauma, a spinal cord tumor, or a tethered cord. The classic presentation is a dissociated sensory loss (pain and temperature loss with preservation of light touch, vibration, and proprioception) in the neck and arms. Symptoms classically appear in late adolescence or early adulthood and progress sporadically with intermittent stable periods.[7] A cervical lesion produces a cape-like pattern of sensory loss of the arms and shoulder, sometimes accompanied by atrophy of the hands and arms, with hypertonia and hyperreflexia in the legs. Extension into the medulla may cause lower cranial neuropathies. The diagnosis is best confirmed by MRI.

TREATMENT

Patients with an associated Chiari II malformation may require posterior fossa decompression and shunting of secondary hydrocephalus. Occasionally, a large syrinx unassociated with a Chiari malformation may require shunting of the syrinx.

BRAIN MALFORMATIONS

DISORDERS OF VENTRAL INDUCTION

Brain malformations develop during the first trimester. Disorders of ventral induction include holoprosencephaly, septo-optic dysplasia, and agenesis of the corpus callosum. Holoprosencephaly results from failure of the prosencephalon to divide, thereby resulting in alobar holoprosencephaly (cortex with a single ventricle) or lobar holoprosencephaly (cerebral hemispheres are mostly separated except for the frontal lobes).

HOLOPROSENCEPHALY

Holoprosencephaly occurs in some individuals with trisomy 13 or 18 or in association with single gene mutations (e.g., *SHH, ZIC2,* and *SIX3*). Holoprosencephaly is often associated with facial dysmorphism. Abnormal temperature regulation and disrupted sleep cycles are common. Central diabetes insipidus occurs in about two thirds of patients with classic holoprosencephaly, whereas deficiencies of growth hormone, thyrotrophic hormone, or adrenocorticotrophic hormone occur less frequently.

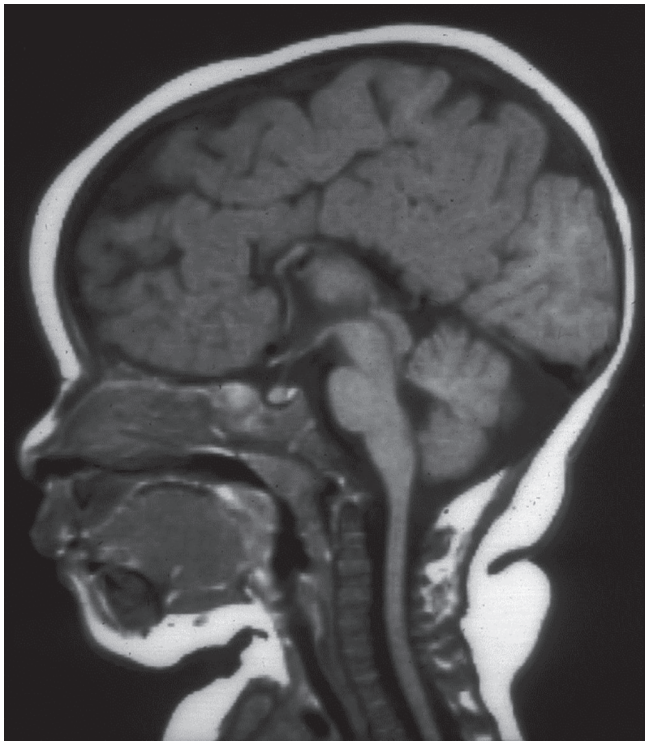

FIGURE 385-3. Midline sagittal view magnetic resonance scan from a child with a near-complete absence of the corpus callosus. Note also the abnormal gyral pattern of the interhemispheric cortex.

Although lobar holoprosencephaly may have a milder phenotype than alobar holoprosencephaly, all patients will experience substantial cognitive impairment and many will develop intractable epilepsy. It is important to identify and treat any associated endocrine dysfunction.

SEPTO-OPTIC DYSPLASIA

Septo-optic dysplasias characterized by optic nerve hypoplasia with visual impairment and variable absence of the septum pellucidum and corpus callosum. It is often associated with pituitary aplasia.[8] Septo-optic dysplasia arises from a variant of *HESX1* on chromosome 3p14. As with holoprosencephaly, septo-optic dysplasia is often associated with endocrine abnormalities, most notably growth hormone deficiency and less frequently hypothyroidism, central diabetes insipidus, and adrenal insufficiency.

AGENESIS OF THE CORPUS CALLOSUM

Complete congenital agenesis of the corpus callosum is rare, but partial absence or hypoplasia of the structure are relatively common. Disruption of brain development by an intrauterine infection or exposure to alcohol can alter the formation of the corpus callosum. Agenesis can be inherited as either an autosomal dominant or an autosomal recessive trait, or it can occur as a component of disorders such as septo-optic dysplasia or the X-linked dominant condition Aicardi syndrome. Often, however, a specific cause of aberrant development of the corpus callosum is not apparent.

An abnormal or missing corpus callosum (Fig. 385-3) is usually discovered on neuroimaging performed to evaluate seizures or developmental delay. Isolated absence or hypoplasia of the corpus callosum can cause few symptoms, but it is often a harbinger of more widespread defects in brain development.[9] Consequently, many individuals with callosal abnormalities have epilepsy, impaired cognition and development, or motor dysfunction.

DISORDERS OF NEURONAL MIGRATION

Disrupted neuronal migration during the second to the fourth month of gestation causes a spectrum of anomalies, including lissencephaly, polymicrogyria, and pachygyria. These disorders also are often associated with hypoplasia of the corpus callosum. Migrational abnormalities have been documented with intrauterine infections, multiple different single gene mutations (e.g., *FLNA DCX, TUBA1A, APC2*), or antenatal exposure to alcohol.

Lissencephaly is characterized by a thickened, smooth-appearing cortex with scant gyral and sulcal development. Band heterotopia and periventricular nodular heterotopia represent less complete migrational abnormalities featuring less severe manifestations than those of lissencephaly. As the name suggests, polymicrogyria is characterized by the occurrence of an excessive number of very small gyri, whereas pachygyria describes a small number of gyri that are too broad. When affecting the entire cortex, all of these anomalies are associated with severe neurologic dysfunction with marked cognitive impairment and often refractory epilepsy. However, very localized migrational abnormalities may allow near normal function, and such focal lesions lend themselves to surgical treatment of epilepsy. Interestingly, subtle migrational anomalies are often identified microscopically in cortical tissue that has been removed during epilepsy surgery, even in individuals whose neuroimaging was unremarkable.

Brain malformations and migrational abnormalities can usually be confirmed with MRI. However, less severe migrational abnormalities may not be obvious on routine neuroimaging.

TREATMENT

Epilepsy resulting from migrational abnormalities is often medically intractable, but some patients respond to antiseizure medications (Chapter 372), vagus nerve stimulation, or a low-glycemic diet. Individuals with very localized cortical dysplasia may benefit from resective epilepsy surgery.

CEREBRAL PALSY

Cerebral palsy is a nonprogressive developmental abnormality that causes permanent disorders of movement and posture. This syndrome presents in infants and often follows an obvious perinatal insult (e.g., asphyxia, intrauterine infection, hemorrhage, prematurity, or brain infarction) or is associated with anatomic abnormalities (e.g., congenital absence of the corpus callosum). However, about 20% of cases are idiopathic, and about one third of such patients have clinically significant, usually de novo, copy number variants.[10] The clinical syndrome is demonstrated by exaggerated reflexes, involuntary movements, and spasticity. About 50% of patients have cognitive impairment, sometimes severe.

TREATMENT

Treatment focuses on managing the hypertonia with oral or intrathecal baclofen, exercise training,[11] intramuscular botulism injections, deep brain stimulation, and selective dorsal rhizotomy.

COGNITIVE DISORDERS

AUTISM SPECTRUM DISORDERS

Autism spectrum disorders are characterized by early-onset impaired social communication and interactions along with repetitive patterns of behavior, interests, or activities. Although autism spectrum disorder is increasingly diagnosed, it is unclear whether this increased prevalence stems from increased recognition and diagnosis or from a truly increased incidence. The cause of autism in most patients is not usually known, but it commonly occurs with genetic conditions such as Rett syndrome, fragile X syndrome, and tuberous sclerosis complex. Other gene variants are less commonly associated with autism spectrum disorder, and the recurrence risk of autism in subsequent siblings is about 5 to 6%.

Prenatal exposure to chemicals such as lead, mercury, toluene, and polychlorinated biphenyls may increase the risk of autism, but it is often difficult to establish causation in a specific individual. However, the administration of childhood vaccines has been definitively shown not to increase the risk of autism.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms can range from mild to severe. Children typically have impaired nonverbal communication, poor eye contact, and an apparent lack of empathy. Affected individuals crave a predictable routine, often becoming upset at the slightest deviation from their expectations; they often exhibit repetitive stereotypical motor mannerisms such as arm flapping or walking in circles. The diagnostic criteria for autism spectrum disorder require evidence of impaired communication and social interaction, as well as two examples of persistent repetitive behaviors or an overly restricted range of interests (Table 385-1).

TREATMENT

Early therapy tends to be more effective, although complete obliteration of the symptoms is not usually feasible.[12] Behavioral therapy can reduce the undesirable behaviors and facilitate more appropriate behaviors. Speech therapy is indicated for individuals with language delay. Most children with autism spectrum disorder require an individualized educational plan. Pharmacotherapy does not effectively reduce the primary manifestations of autism spectrum disorder, but drug therapy may help comorbid conditions such as attention deficit disorder (Chapter 362), aggression, anxiety, oppositional behavior, and obsessive-compulsive behaviors (Chapter 362).

PROGNOSIS

Autism spectrum disorder is a chronic condition, and symptoms persist into adulthood. The severity largely determines the patient's functional outcome. Individuals with mildly impaired social communication and interaction can often function with targeted support, whereas children with little language, limited social adaptability, and great difficulty adjusting to change typically respond less effectively to treatment. The presence of comorbid conditions such as cognitive impairment, psychiatric disorders, or epilepsy can further worsen the prognosis.

RETT SYNDROME

With a prevalence of 1 in 10,000 female births, Rett syndrome is one of the most common monogenetic causes of cognitive impairment. Rett syndrome is an X-linked dominant disorder caused by variant in the *MECP2* gene.[13] The vast majority of affected individuals arise via a spontaneous mutation. The MeCP2 protein is particularly abundant in the brain, where it likely facilitates the development and maintenance of synaptic connections. Mutational analysis has allowed the recognition of a broad spectrum of clinical severity, ranging from learning disability to severe encephalopathy.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Girls with classic Rett syndrome develop normally for the first 6 to 18 months, then undergo deceleration of head growth and rapid loss of previously acquired developmental skills. Function eventually stabilizes, with residual microcephaly, loss of language, and diminished purposeful hand movements. Patients often exhibit stereotypical hand wringing (or "hand washing") movements. Epilepsy and behavioral abnormalities are common. With the typical loss of language, the manifestations of Rett syndrome resemble those of autism, although with notable preservation of eye contact. Late manifestations include spasticity, gait apraxia, and scoliosis. Live-born hemizygous males have earlier and more severe symptoms, typically presenting with neonatal epileptic encephalopathy, microcephaly, abnormal tone, irregular breathing, and macroorchidism.

Diagnosis of Rett syndrome is confirmed by mutational analysis. An electrocardiogram should be obtained because QTc prolongation is common.

FIGURE 385-4. A young woman with the characteristic facial appearance of Down syndrome.

TABLE 385-1 DIAGNOSTIC CRITERIA FOR AUTISM SPECTRUM DISORDER

1. Deficits in Social Communication/Interaction (must have all three criteria):
   a. Problems reciprocating social or emotional interaction, including difficulty establishing or maintaining back-and-forth conversations and interactions, inability to initiate an interaction, and problems with shared attention or sharing of emotions and interests with others
   b. Severe problems maintaining relationships—ranges from lack of interest in other people to difficulties in pretend play and engaging in age-appropriate social activities, and problems adjusting to different social expectations
   c. Nonverbal communication problems such as abnormal eye contact, posture, facial expressions, tone of voice, and gestures, as well as an inability to understand these
2. Restricted and Repetitive Behavior (at least two criteria must be met):
   a. Stereotyped or repetitive speech, motor movements, or use of objects
   b. Excessive adherence to routines, ritualized patterns of verbal or nonverbal behavior, or excessive resistance to change
   c. Highly restricted interests that are abnormal in intensity or focus
   d. Hyperreactivity or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment

Symptoms must be present in early childhood but may not become fully manifest until social demands exceed capacities. Symptoms need to be *functionally impairing* and not better described by another DSM-5 diagnosis.

DSM-5 = *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Publishing; 2013.

TREATMENT AND PROGNOSIS

In one study, trofinetide (an analogue of neuropeptide (1-3) IGF at 200 mg twice daily) significantly improved functional status but did not restore normal function.[A1] Treatment of epilepsy (Chapter 372) and spasticity is beneficial. An annual electrocardiogram to monitor for prolonged QTc is appropriate. Early death is common in hemizygous males. Affected females often live well into middle age and beyond, although information about survival beyond middle age is limited.

FRAGILE X SYNDROME

Fragile X syndrome is another common genetic cause of intellectual disability. Most instances of fragile X syndrome are due to expanded trinucleotide (CGG) repeats in the first exon of the X-linked *FMR1* gene. Individuals with more than 200 CGG repeats have a high likelihood of exhibiting the classic manifestations of fragile X syndrome, whereas those with 55 to 200 repeats may remain asymptomatic or exhibit a milder phenotype.[14] Similarly, female carriers typically exhibit less severe cognitive and behavioral symptoms.

Affected individuals have a distinctive phenotype, characterized by macrocephaly, a long narrow face, prominent ears, pubertal macroorchidism, and joint laxity. Cognitive impairment, autism spectrum disorder, and attention deficit disorder are common. Diagnosis is confirmed by genetic testing.

TREATMENT AND PROGNOSIS

A recent small randomized trial of oral trofinetide (70 mg/kg twice daily) yielded encouraging preliminary results.[A2] The severity of fragile X syndrome manifestations varies, in part because of the number of CGG repeats in a given individual. Most males have marked cognitive and behavioral dysfunction. Manifesting females typically experience milder symptoms than male patients. Longitudinal studies suggest that cognitive development plateaus in adolescence and then tends to decline by adulthood. The mechanism for this decline is incompletely understood, and it is not yet clear whether trofinetide can prevent this decline.

DOWN SYNDROME (TRISOMY 21)

With a frequency of 1 in 700 newborns, Down syndrome is the most common chromosomal anomaly as well as the most common genetic cause of intellectual disability.[15] The incidence of Down syndrome increases with advanced maternal age at the time of conception. Down syndrome results from complete or partial duplication of chromosome 21. Approximately 95% of the individuals with Down syndrome have trisomy 21. The remaining cases are related to a translocation (4%) or mosaicism (1%) involving chromosome 21.

Individuals with Down syndrome exhibit a characteristic phenotype (Fig. 385-4), although both the findings and their severity vary. Newborns typically exhibit hypotonia, a short neck, an upward slant of the eyes, and a single deep crease across the palms. Delayed motor and cognitive milestones are apparent early, and variable intellectual disability is characteristic, although most individuals are able to attend school with the appropriate accommodations and manage some activities of daily living.

Down syndrome is associated with a variety of complications, many of which result in neurologic dysfunction. Affected individuals have an increased risk of hypothyroidism (Chapter 207), epilepsy (Chapter 372), and acute lymphocytic leukemia (Chapter 168). Many individuals with Down syndrome have congenital heart anomalies (especially endocardial cushion defects, atrial septal defects, and ventricular septal defects; Chapter 55), which in turn introduce a risk of cerebral embolism and stroke. Stroke can also arise from progressive carotid vasculopathy (moyamoya syndrome). About 10 to 20% of individuals with Down syndrome have atlantoaxial instability, and about a third of such individuals later develop premature cervical spondylosis, thereby further increasing the risk of spinal cord dysfunction. Approximately 1 to 2% of individuals with Down syndrome develop symptomatic spinal cord dysfunction.

The gene encoding amyloid precursor protein is on chromosome 21, and a mutation of this gene is responsible for a hereditary form of Alzheimer disease (Chapter 371). By age 40, many individuals with Down syndrome have beta amyloid brain plaques and tau tangles. An estimated 30% of individuals with Down syndrome develop dementia by age 60 years and 50% by age 70 years. The baseline cognitive impairment of individuals with Down syndrome can make early diagnosis of dementia challenging. Many people initially present not with memory loss but with diminished attention, loss of enthusiasm, behavior change, or withdrawal.

The diagnosis is usually clinically evident, but it should be confirmed by chromosomal analysis.

TREATMENT

No targeted therapy currently exists for Down syndrome. Nevertheless, the prognosis for these individuals has improved considerably owing to improved recognition and management of conditions such congenital heart disease, spine defects, and leukemia.[16] Screening for cervical spine instability is recommended before general anesthesia and before allowing participation in activities that might aggravate atlantoaxial instability. It is important to eliminate potentially treatable causes of cognitive change, particularly hypothyroidism (Chapter 207). Appropriate educational programs, good medical care, and a supportive environment allow most patients to lead enjoyable lives.

NEUROCUTANEOUS DISORDERS

Neurocutaneous syndromes are congenital, often hereditary, disorders that feature lesions of both the skin and the nervous system.[17] Although these disorders have distinctive clinical findings and unique pathogenic mechanisms (Table 385-2), the term neurocutaneous syndrome has persisted in part because it facilitates recognition of these rare conditions.

TUBEROUS SCLEROSIS COMPLEX

The incidence of tuberous sclerosis complex is about 1 in 6000. Tuberous sclerosis complex is inherited as an autosomal dominant trait, although sporadic mutations account for up to 75% of the affected patients. The two tuberous sclerosis complex genes are *TSC1* at 9q34.3 (coding for hamartin) and *TSC2* at 16p13.3 (coding for tuberin). A mutation of either gene leads to upregulation of the mammalian target of rapamycin (mTOR), which promotes cell growth, proliferation, neuronal migration, and angiogenesis.[18] Although the clinical manifestations are similar, *TSC2* mutations tend to cause a more severe phenotype than *TSC1* mutations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Multiple organs can be affected, including the brain (cortical tubers, subependymal giant cell astrocytomas), heart (cardiac rhabdomyomas), skin (facial angiofibromas, hypomelanotic ["ash leaf"] macules, shagreen patches, and ungual fibromas), kidneys (renal angiomyolipomas), eye (retinal hamartomas), and lung (lymphangioleiomyomatosis; Chapter 78).[19] Brain imaging typically shows subependymal nodules and cortical tubers (Fig. 385-5). The manifestations of tuberous sclerosis complex are highly variable, even among affected members of the same family, and many of its complications are age-related. Cardiac rhabdomyomas typically present as obstructive heart failure in neonates. Seizures, often infantile spasms, usually begin during the first year of life, then persist. Lymphangioleiomyomatosis often presents with a spontaneous pneumothorax (Chapter 86) and, if untreated, can progress to respiratory failure. It is strikingly more common among women and usually remains asymptomatic until adolescence or adulthood.

The diagnosis of tuberous sclerosis complex is generally apparent from the clinical manifestations (Table 385-3), but genetic testing is useful in atypical cases and for genetic counseling.

TREATMENT

The mTOR inhibitors everolimus and sirolimus have dramatically altered the natural history of tuberous sclerosis complex. Everolimus (10 mg/day) reduces the size of angiomyolipomas in about 40% of treated patients, and everolimus (titrated to 5 to 15 ng/mL) also reduces the size of subependymal giant cell astrocytomas by at least 50% in about one third of treated patients.

Unfortunately, lesions promptly regrow when the medication is halted. Topical rapamycin can shrink facial angiofibromas,[A3] and the topical combination of 0.1% rapamycin plus 0.0003% calcitriol may be even better.[A4] Sirolimus (under expert supervision at a typical adult maintenance dose of 2 mg/day) is also approved for use in individuals with lymphangioleiomyomatosis.

Everolimus is also approved for treatment of intractable epilepsy due to tuberous sclerosis complex,[A5] but it is used infrequently due to its cost and limited effectiveness. Increasing evidence supports starting treatment of tuberous sclerosis complex-related epilepsy even before the onset of clinical seizures to reduce the severity of the epilepsy and the associated cognitive impairment.[A6] Vigabatrin is recommended for the initial treatment of infantile spasms due to tuberous sclerosis complex. If the onset of seizures can be localized to one or two areas of cortical dysplasia, surgical resection may be effective.

TABLE 385-2 SELECTED NEUROCUTANEOUS DISORDERS

DISORDER	INHERITANCE	GENE/CHROMOSOME	CLINICAL MANIFESTATIONS
Tuberous sclerosis	AD	*TSC1*/9q34.4 *TSC2*/16p13.3	Cutaneous: Hypomelanotic macules, facial angiofibromas, periungual fibromas, shagreen patch, ungual fibromas Neurologic: Epilepsy (often infantile spasms), multiple subependymal nodules, multifocal cortical dysplasias, cognitive impairment, autism spectrum disorder; giant cell astrocytoma Other: Lymphangioleiomyomatosis, renal angiomyolipomas, retinal hamartomas, cardiac rhabdomyomas
Neurofibromatosis 1	AD	*NF1*/17q11.2	Cutaneous: Café-au-lait spots, axillary freckling, cutaneous neurofibromas Neurologic: Learning disorders, attention deficit disorder, cerebral vasculopathy, optic nerve glioma, and other cerebral tumors Other: Lisch nodules of the iris, pheochromocytoma, renal artery stenosis, macrocephaly, skeletal anomalies
Neurofibromatosis 2	AD	*NF2*/22q12.2	Cutaneous: Plaque-like intracutaneous tumor; nodular nerve tumors; café-au-lait macules (in about 40%) Neurologic: Bilateral cranial nerve VIII schwannomas with progressive deafness; other tumors, including meningiomas, ependymomas, and astrocytomas Other: Cataracts
Sturge-Weber syndrome	Sporadic (SM)	*GNAQ*/9q21	Cutaneous: Upper facial port-wine nevus Neurologic: Leptomeningeal angioma, epilepsy, variable cognitive impairment Other: Glaucoma
Hereditary hemorrhagic telangiectasia (Chapter 159)	AD	*ENG*/9q34.11 *ALK1*/12q13 Rare other loci	Cutaneous: Telangiectasias of nasal mucosa, tongue, earlobes, extremities Neurologic: Cerebral arteriovenous malformation; paradoxical embolism with stroke; cerebral abscess Other: Pulmonary arteriovenous fistulas; nosebleeds; gastrointestinal hemorrhage
Ataxia telangiectasia (Chapter 231)	AR	*ATM*/11q22.3	Cutaneous: Telangiectasias especially of the sclera, face and the antecubital and popliteal fossa Neurologic: Early-onset progressive ataxia and oculomotor apraxia; later onset of chorea and dystonia Other: Deficient immunoglobulins with frequent infections; risk of leukemia, lymphoma and other malignancies
PHACE syndrome	Sporadic (Likely SM)	Unknown	Cutaneous: Hemangiomas of face and scalp Neurologic: Cerebellar anomalies; anomalies of the brain arteries Other: Female predominance; anomalies of the heart, eye, and sternum
Pseudoxanthoma elasticum (Chapter 239)	AR	*ABCC6*/16p13.11	Cutaneous: Plaque-like yellowish lesions of the neck, axillae, and popliteal or antecubital fossae Neurologic: Cerebral vasculopathy with single or multiple infarctions, intracranial aneurysms Other: Angioid retinal streaks with retinal hemorrhage or retinal detachment, gastrointestinal hemorrhage
Neurocutaneous melanosis	Sporadic (SM)	*NRAS*/1p13.2	Cutaneous: Giant melanocytic nevus, often with satellite nevi that occasionally undergo transformation to melanoma. Neurologic: Melanosis of CNS, occasional hypotonia and epilepsy, rare melanoma
Incontinentia pigmenti	XLD	*IKBKG*/Xq28	Cutaneous: Inflammatory vesicular rash (neonates) evolving to verrucous lesions, then a swirling marbled hyperpigmentation pattern in older patients Neurologic: Recurrent neonatal strokes with cystic encephalomalacia, variable epilepsy and cognitive impairment Other: Dental anomalies, thin hair, retinal vascular changes and risk of retinal detachment
Menkes disease	XLR	*ATP7A*/Xq21.1	Cutaneous: Sparse fragile hair with characteristic kinky appearance Neurologic: Severe epileptic encephalopathy and profound cognitive impairment Other: Arterial tortuosity, growth failure

AD = autosomal dominant; AR = autosomal recessive; CNS = central nervous system; PHACES = **P**osterior fossa malformations, **H**emangiomas of face and scalp, **A**rterial anomalies (cerebral or cervical vessels), **C**ardiac anomalies, **E**ye anomalies, **S**ternal anomalies; SM = somatic mosaicism; XLD = X-linked dominant; XLR = X-linked recessive.

NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis type 1 is an autosomal dominant disorder with a prevalence of 1 in 3000 births. Almost 50% of the cases arise from sporadic mutations. The *NF1* gene (chromosome 17q11.2) expresses neurofibromin, a tumor suppressor protein. Loss of neurofibromin expression leads to dysregulation of cell growth and differentiation.[20] There is no consistent genotype-phenotype correlation.

About 50% of affected patients have learning disabilities. Subcutaneous neurofibromas may be disfiguring and can be painful. Patients may have plexiform neurofibromas, tibial dysplasia, and vasculopathy. Affected patients also have an increased risk of malignant peripheral nerve sheath tumors and central nervous system gliomas, as well as other tumors, with a 60% lifetime risk of cancer. Other manifestations include attention deficit disorder, macrocephaly, and epilepsy. Important complications include scoliosis, gastrointestinal neurofibromas, pheochromocytomas (Chapter 209), and renal artery stenosis (Chapter 110).

The criteria for the diagnosis of neurofibromatosis type 1 include two or more of the following: (1) six or more café-au-lait macules (Fig. 385-6) larger than 5 mm in prepubertal patients or more than 15 mm in postpubertal individuals, (2) two or more neurofibromas (Fig. 385-7) of any type or one plexiform neurofibroma, (3) axillary or inguinal freckling, (4) sphenoid bone dysplasia, (5) optic nerve glioma, (6) Lisch nodules (pigmented hamartomas in the iris), and (7) a family history of neurofibromatosis type 1. Mutational analysis is not required for diagnosis but may be useful in individuals with less severe or atypical manifestations.

TREATMENT

Many individuals with neurofibromatosis type 1 do not require treatment, and many others need treatment only for low-level symptoms. However, all patients require periodic surveillance because of these associated risks (Table 385-4). Genetic counseling is recommended for all patients and their families.

Surgery can be successful for subcutaneous, intraspinal, or intracranial lesions. The MEK inhibitor selumetinib (25 mg/m^2 twice daily in 28-day cycles)[21] can reduce the size of inoperable plexiform neurofibromas.[A7] Optic nerve gliomas may be treated with cisplatin or temozolomide. Radiation is not recommended. Selumetinib and other MEK inhibitors have also shown promise in individuals with low-grade astrocytoma, spinal neurofibromas, and even cognitive dysfunction.[22]

NEUROFIBROMATOSIS TYPE 2

Neurofibromatosis type 2 is inherited as autosomal dominant trait and occurs in approximately 1 in 50,000 individuals, with clinical onset usually in young adulthood. Although classified as a subtype of neurofibromatosis and usually included with the neurocutaneous disorders, neurofibromatosis type 2 bears little resemblance to neurofibromatosis type 1. The *NF2* gene, which is located on chromosome 22q, codes for merlin, a cytoskeletal protein. Most patients eventually develop bilateral cranial nerve VIII nerve schwannomas (Fig. 385-8), although these tumors often begin as unilateral lesions. Multiple meningiomas are also common,[23] whereas ependymomas and gliomas occur less frequently.

Skin lesions are present in a minority of patients with neurofibromatosis type 2, and the diagnosis is based on the following criteria: (1) bilateral cranial nerve VIII nerve tumors detected by MRI, (2) a family member with either neurofibromatosis type 2 or unilateral cranial nerve VIII nerve schwannoma, and (3) juvenile posterior subcapsular lens opacities.

TREATMENT

Removal of the schwannomas and other tumors is usually indicated, although preservation of hearing is challenging even with early surgery. Bevacizumab (a vascular endothelial growth factor inhibitor at 5 mg/kg intravenously every 2 weeks) can improve hearing in some patients who have vestibular schwannomas, but its role remains uncertain.[24] Family genetic counseling is often helpful.

STURGE-WEBER SYNDROME

Sturge-Weber syndrome is characterized by an upper facial vascular nevus (port-wine stain; Fig. 385-9), a leptomeningeal angioma, and variable ocular abnormalities (glaucoma and choroidal hemangioma). The disorder occurs sporadically in approximately 1 in 20,000 births. The syndrome results from a somatic mutation of *GNAQ* on chromosome 9q21.[25]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of Sturge-Weber syndrome are highly variable. Only individuals with a port-wine stain of the upper face and periorbital area develop the leptomeningeal angioma, but only about 15% of people with an upper facial nevus have brain involvement. Glaucoma can occur even in the absence of neurologic involvement. Neurologic manifestations most often include focal-onset epilepsy and variable cognitive impairment. Less common features include hemiparesis, hemianopia, or other focal finings. Calcium deposition within the cerebral cortical layers explains the classic "trolley track" radiographic calcification pattern of Sturge-Weber syndrome, although this finding is often absent, especially in infants.

The diagnosis of Sturge-Weber syndrome rests on the clinical findings because the somatic mosaic gene mutation is not detectable on blood-based

TABLE 385-3 DIAGNOSTIC CRITERIA FOR TUBEROUS SCLEROSIS COMPLEX

Definite—Two major features or one major feature plus two minor features
Probable—One major feature plus one minor feature
Possible—One major feature or two or more minor features

MAJOR FEATURES
Facial angiofibromas or forehead plaque
Nontraumatic ungual or periungual fibromas
More than three hypomelanotic macules (ash leaf spots)
Shagreen patch (connective tissue nevus)
Multiple retinal nodular hamartomas
Cortical tuber
Subependymal nodule
Subependymal giant cell astrocytoma
Cardiac rhabdomyoma, single or multiple
Lymphangiomyomatosis
Renal angiomyolipoma
MINOR FEATURES
Multiple dental enamel pits
Hamartomatous rectal polyps
Bone cysts
Cerebral white matter radial migration lines
Gingival fibromas
Nonrenal hamartoma
Retinal achromic patch
"Confetti" skin lesions
Multiple renal cysts

Reproduced with permission from Northrup H, Aronow ME, Bebin EM, et al. Updated international tuberous sclerosis complex diagnostic criteria and surveillance and management recommendations. *Pediatr Neurol.* 2021;123:50-66.

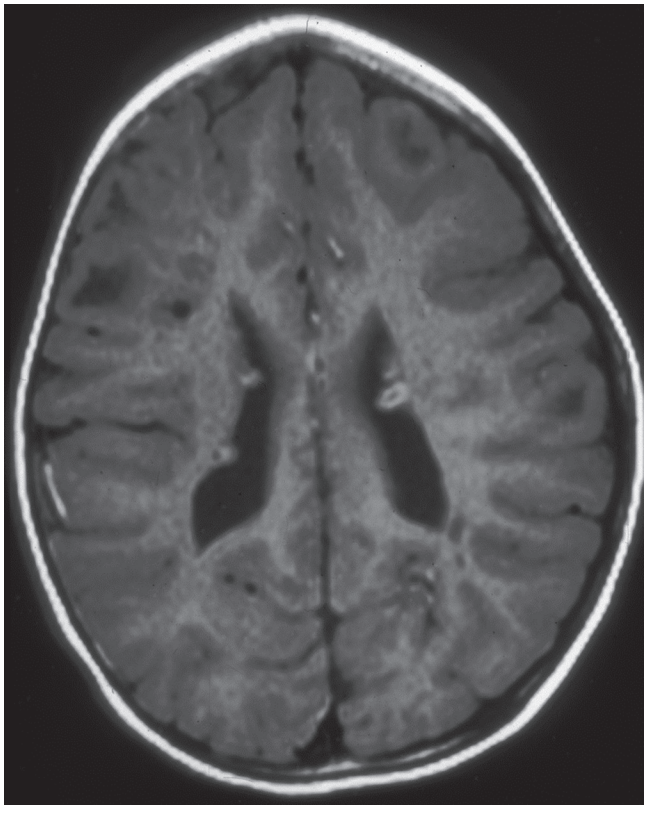

FIGURE 385-5. Magnetic resonance imaging depicts subependymal nodules and multiple cortical tubers in a patient with tuberous sclerosis complex.

FIGURE 385-6. Café-au-lait macules in a child with neurofibromatosis type 1. Note also the presence of axillary freckling.

FIGURE 385-7. **Multiple neurofibromas covering the back of a patient with neurofibromatosis type 1.**

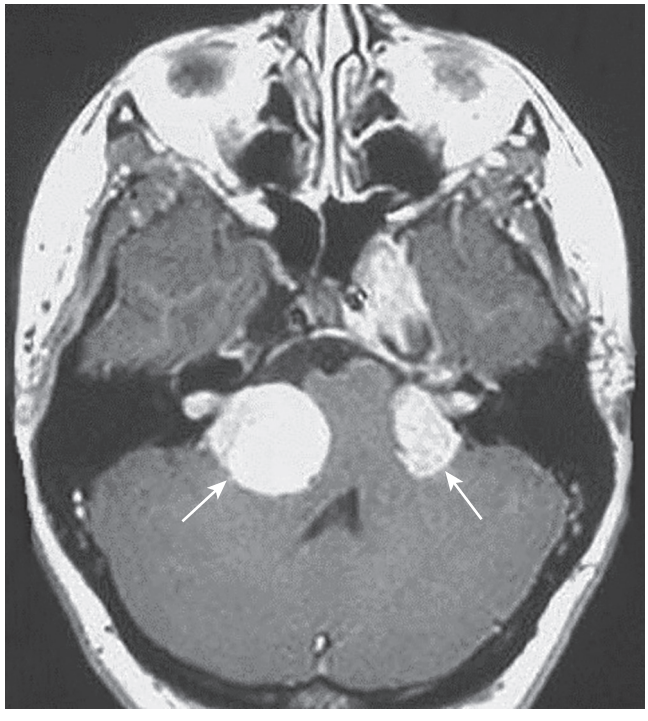

FIGURE 385-8. **Bilateral cranial nerve VIII nerve schwannomas *(arrows)* due to neurofibromatosis type 2.**

TABLE 385-4 RECOMMENDED SURVEILLANCE IN PATIENTS WITH NEUROFIBROMATOSIS TYPE 1

Annual physical examination by a physician who is familiar with the individual and with the disease
Annual ophthalmologic examination in early childhood, less frequent examination in older children and adults
Regular developmental assessment by screening questionnaire (in childhood)
Regular blood pressure monitoring
Other studies only as indicated on the basis of clinically apparent signs or symptoms
Monitoring of those who have abnormalities of the central nervous system, skeletal system, or cardiovascular system by an appropriate specialist

Adapted from Miller DT, Freedenberg D, Schorry E, et al. Health supervision for children with neurofibromatosis type 1. *Pediatrics*. 2019;143:e20190660.

FIGURE 385-9. **Sturge-Weber syndrome.** This man has a classic capillary hemangioma affecting the right face and extending posteriorly beneath the hairline. The hemangioma often thickens as the patient ages, thereby resulting in the nodular appearance shown here.

gene testing. The upper facial nevus is obvious at birth. Neuroimaging can identify brain involvement prior to the onset of neurologic symptoms. Computed tomography can demonstrate the brain calcification, but MRI with contrast more reliably demonstrates the intracranial vascular lesion.

TREATMENT

Laser treatments can render the nevus less obvious. Periodic screening for glaucoma is essential, even into adulthood. Uncontrolled epilepsy likely contributes to long-term cognitive impairment; if antiepileptic drugs are ineffective, surgical excision of epileptogenic region may be considered.

PROGNOSIS

The prognosis of individuals with Sturge-Weber syndrome varies depending on the severity of their manifestations. Patients with good seizure control and near-normal cognition function normally and can have a normal lifespan. Individuals with intractable epilepsy and severe intellectual disability, in contrast, have a shorter life expectancy but can still live well into adulthood.

VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau disease is an autosomal dominant disorder caused by a defective tumor suppressor *(VHL)* at chromosome 3p25-p26.[26] Clinical manifestations, which usually begin in the third or fourth decade, include retinal angiomas (with retinal inflammation and detachment), hemangioblastomas of the brain (usually cerebellar) and spinal cord, angiomas of the liver and kidney, renal cell carcinomas (Chapter 182), pheochromocytomas (Chapter 209), endolymphatic sac tumors, and cysts of the pancreas, kidney, liver, and epididymis. Retinal and cerebellar symptoms (headache, vertigo, vomiting, ataxia, and dysmetria) are common.

Clinical diagnosis is suggested based on the presence of more than one brain hemangioblastoma, one hemangioblastoma with a visceral manifestation of the disease, or one disease manifestation plus a known family history. Genetic testing detects mutations in the *VHL* gene in essentially all affected individuals.

TREATMENT

Recommended surveillance includes an annual ophthalmologic examination, annual blood pressure monitoring, screening for pheochromocytoma (Chapter 209) every 5 years in affected families, and annual abdominal ultrasound examination beginning at age 16 years. Treatment is symptomatic for retinal detachments. Brain tumors (Chapter 175), renal cell carcinomas (Chapter 182), pheochromocytomas (Chapter 209), epididymal tumors (Chapter 185), and endolymphatic sac tumors should be treated surgically, but smaller central nervous system tumors may be treated by gamma knife. Pazopanib (a tyrosine kinase inhibitor that inhibits angiogenesis) at 800 mg per day may be useful in patients who have progressive lesions,[27] and belzutifan (120 mg daily) has shown promise for treating renal cell carcinomas in this syndrome.[28]

386 AUTONOMIC DISORDERS

EDUARDO E. BENARROCH AND ROY FREEMAN

SYSTEMIC AUTONOMIC DISORDERS

DEFINITION

Autonomic dysfunction, which is an important cause of disability, accompanies many diseases that affect the central or peripheral nervous system. It may manifest as autonomic failure or autonomic hyperactivity, may be generalized or focal, and may have a subacute, chronic progressive, or intermittent temporal profile.[1] The prognosis of autonomic disorders depends on the underlying condition.

EPIDEMIOLOGY

The most common causes of autonomic failure are neurodegenerative disorders and autonomic neuropathies. Multiple system atrophy (Chapters 378 and 379), which is the most common central neurodegenerative disorder associated with severe autonomic failure,[2] has an estimated incidence of 0.6 per 100,000 persons per year and a prevalence of 3 per 100,000 in persons older than age 50 years. Autonomic failure may also occur in the other central neurodegenerative diseases, such as Parkinson disease (Chapter 378) and Lewy body dementia (Chapter 371), associated with deposition of the protein alpha-synuclein.

By comparison, the most common cause of autonomic neuropathy in the developed world is diabetes mellitus[3] (Chapter 210), but clinically important peripheral neurodegenerative disease is also seen with amyloid deposition (Chapter 174) as well as inherited neuropathies (Chapter 388). After 10 years with type 2 diabetes (Chapter 210), autonomic impairment is detected by abnormal heart rate variability in 65% of patients, and orthostatic hypotension is seen in about 25% of patients. The incidence of light chain (AL) amyloidosis (Chapter 174) is approximately 12 cases per million persons per year, with an estimated prevalence of 30,000 to 45,000 cases per million persons; peripheral nerve involvement occurs in 22% of cases.[4] The incidence of variant amyloid transthyretin (ATTR) amyloidosis is estimated at 0.3 cases per million persons per year, with an estimated prevalence of 5.2 cases per million persons. Although rare, an important cause of hereditary autonomic neuropathy is hereditary sensory and autonomic neuropath type III (HSAN-III), also known as familial dysautonomia or Riley-Day syndrome. This autosomal recessive disorder is seen primarily in Ashkenazi Jewish children, with an incidence of 1 in 3700 live births and a carrier frequency of 1 in 32 individuals in this population.

PATHOBIOLOGY

The three components of the autonomic system are the sympathetic, parasympathetic, and enteric nervous systems.[5] The sympathetic and parasympathetic outputs are mediated by preganglionic neurons located in the spinal cord or brainstem, as well as by neurons that are located in autonomic ganglia and project to the target organs. Preganglionic neurons activate the autonomic ganglion neurons by releasing acetylcholine, which acts via ganglion-type nicotinic acetylcholine receptors. Sympathetic output depends on preganglionic neurons that are located at the T1-L2 segments of the spinal cord and that activate neurons in the paravertebral and prevertebral ganglia, as well as in the adrenal medulla. The sympathetic division is critical for maintenance of arterial blood pressure, regulation of regional blood flow, thermoregulation, the response to exercise, homeostatic challenges, and external stressors.[6] The primary sympathetic neurotransmitter, which is norepinephrine, acts via $\alpha 1$ receptors to elicit vasoconstriction, pupillary dilation, and smooth muscle contraction in the bladder detrusor muscle and vas deferens; $\beta 1$ receptors to elicit cardiac stimulation (tachycardia and increased stroke volume); and $\beta 2$ receptors to elicit relaxation of vascular and visceral smooth muscle. The sympathetic output to the sweat glands is mediated by acetylcholine acting via muscarinic M3 receptors.

Parasympathetic output is critical for reflex control of organs via their effects on local ganglia that are close to or within the target organ. Output from the Edinger-Westphal nucleus, mediated by the oculomotor nerve via the ciliary ganglion, controls accommodation and the pupillary light reflex. Outputs from the salivatory nuclear complex—mediated by the facial and glossopharyngeal nerves via the sphenopalatine, submaxillary, submandibular, and otic ganglia—control lacrimation and salivation. The vagus nerve provides the most widespread preganglionic parasympathetic output to local respiratory, cardiac, and enteric ganglia. The dorsal motor nucleus of the vagus controls motility and secretion in the respiratory and gastrointestinal tracts and also contributes to control of the heart. Neurons located in the nucleus ambiguus provide vagal output to the heart (cardiovagal output) that is critical for the beat-to-beat control of the heart rate. Vagal outputs inhibit heart rate and atrioventricular conduction via M2 receptors. The parasympathetic output is also mediated by noncholinergic neurons that trigger smooth muscle relaxation and vasodilation primarily via release of nitric oxide and vasoactive intestinal polypeptide.

The sacral preganglionic nucleus innervates the pelvic organs and promotes bladder detrusor contraction for micturition, rectal contraction for defecation, and vasodilation of erectile tissues. The enteric nervous system mediates local reflexes for peristalsis and secretion, both independently and under sympathetic and parasympathetic modulation. The primary neurotransmitter of most parasympathetic and enteric neurons is acetylcholine, which acts via M3 receptors, which in turn promote smooth muscle contraction and glandular secretion.

The two main influences controlling sympathetic and parasympathetic output are reflexes triggered by visceral afferent nerves and the descending modulatory influence from the hypothalamus and brainstem. The baroreceptor reflex (baroreflex) is a critical feedback mechanism for buffering changes in arterial pressure. Inputs from the carotid sinus and baroreceptors in the aortic arch, activated by an increase in pulse pressure, reach the nucleus of the solitary tract, which triggers two responses that reduce blood pressure: activation of vagal output to the heart, thereby leading to decrease of the heart rate; and inhibition of sympathetic output to splanchnic and muscle blood vessels leading to a decrease of total peripheral resistance. Upon standing, unloading of the baroreceptors triggers sympathetically mediated vasoconstriction that limits venous pooling in the abdomen and lower limbs. Failure of this efferent baroreflex sympathetic vasoconstrictor response results in neurogenic orthostatic hypotension (Chapter 49). The primary causes are lesions that affect sympathoexcitatory neurons in the rostral ventrolateral medulla, preganglionic sympathetic neurons, and/or noradrenergic ganglion neurons or their

386 AUTONOMIC DISORDERS

EDUARDO E. BENARROCH AND ROY FREEMAN

SYSTEMIC AUTONOMIC DISORDERS

DEFINITION

Autonomic dysfunction, which is an important cause of disability, accompanies many diseases that affect the central or peripheral nervous system. It may manifest as autonomic failure or autonomic hyperactivity, may be generalized or focal, and may have a subacute, chronic progressive, or intermittent temporal profile.[1] The prognosis of autonomic disorders depends on the underlying condition.

EPIDEMIOLOGY

The most common causes of autonomic failure are neurodegenerative disorders and autonomic neuropathies. Multiple system atrophy (Chapters 378 and 379), which is the most common central neurodegenerative disorder associated with severe autonomic failure,[2] has an estimated incidence of 0.6 per 100,000 persons per year and a prevalence of 3 per 100,000 in persons older than age 50 years. Autonomic failure may also occur in the other central neurodegenerative diseases, such as Parkinson disease (Chapter 378) and Lewy body dementia (Chapter 371), associated with deposition of the protein alpha-synuclein.

By comparison, the most common cause of autonomic neuropathy in the developed world is diabetes mellitus[3] (Chapter 210), but clinically important peripheral neurodegenerative disease is also seen with amyloid deposition (Chapter 174) as well as inherited neuropathies (Chapter 388). After 10 years with type 2 diabetes (Chapter 210), autonomic impairment is detected by abnormal heart rate variability in 65% of patients, and orthostatic hypotension is seen in about 25% of patients. The incidence of light chain (AL) amyloidosis (Chapter 174) is approximately 12 cases per million persons per year, with an estimated prevalence of 30,000 to 45,000 cases per million persons; peripheral nerve involvement occurs in 22% of cases.[4] The incidence of variant amyloid transthyretin (ATTR) amyloidosis is estimated at 0.3 cases per million persons per year, with an estimated prevalence of 5.2 cases per million persons. Although rare, an important cause of hereditary autonomic neuropathy is hereditary sensory and autonomic neuropath type III (HSAN-III), also known as familial dysautonomia or Riley-Day syndrome. This autosomal recessive disorder is seen primarily in Ashkenazi Jewish children, with an incidence of 1 in 3700 live births and a carrier frequency of 1 in 32 individuals in this population.

PATHOBIOLOGY

The three components of the autonomic system are the sympathetic, parasympathetic, and enteric nervous systems.[5] The sympathetic and parasympathetic outputs are mediated by preganglionic neurons located in the spinal cord or brainstem, as well as by neurons that are located in autonomic ganglia and project to the target organs. Preganglionic neurons activate the autonomic ganglion neurons by releasing acetylcholine, which acts via ganglion-type nicotinic acetylcholine receptors. Sympathetic output depends on preganglionic neurons that are located at the T1-L2 segments of the spinal cord and that activate neurons in the paravertebral and prevertebral ganglia, as well as in the adrenal medulla. The sympathetic division is critical for maintenance of arterial blood pressure, regulation of regional blood flow, thermoregulation, the response to exercise, homeostatic challenges, and external stressors.[6] The primary sympathetic neurotransmitter, which is norepinephrine, acts via $\alpha 1$ receptors to elicit vasoconstriction, pupillary dilation, and smooth muscle contraction in the bladder detrusor muscle and vas deferens; $\beta 1$ receptors to elicit cardiac stimulation (tachycardia and increased stroke volume); and $\beta 2$ receptors to elicit relaxation of vascular and visceral smooth muscle. The sympathetic output to the sweat glands is mediated by acetylcholine acting via muscarinic M3 receptors.

Parasympathetic output is critical for reflex control of organs via their effects on local ganglia that are close to or within the target organ. Output from the Edinger-Westphal nucleus, mediated by the oculomotor nerve via the ciliary ganglion, controls accommodation and the pupillary light reflex. Outputs from the salivatory nuclear complex—mediated by the facial and glossopharyngeal nerves via the sphenopalatine, submaxillary, submandibular, and otic ganglia—control lacrimation and salivation. The vagus nerve provides the most widespread preganglionic parasympathetic output to local respiratory, cardiac, and enteric ganglia. The dorsal motor nucleus of the vagus controls motility and secretion in the respiratory and gastrointestinal tracts and also contributes to control of the heart. Neurons located in the nucleus ambiguus provide vagal output to the heart (cardiovagal output) that is critical for the beat-to-beat control of the heart rate. Vagal outputs inhibit heart rate and atrioventricular conduction via M2 receptors. The parasympathetic output is also mediated by noncholinergic neurons that trigger smooth muscle relaxation and vasodilation primarily via release of nitric oxide and vasoactive intestinal polypeptide.

The sacral preganglionic nucleus innervates the pelvic organs and promotes bladder detrusor contraction for micturition, rectal contraction for defecation, and vasodilation of erectile tissues. The enteric nervous system mediates local reflexes for peristalsis and secretion, both independently and under sympathetic and parasympathetic modulation. The primary neurotransmitter of most parasympathetic and enteric neurons is acetylcholine, which acts via M3 receptors, which in turn promote smooth muscle contraction and glandular secretion.

The two main influences controlling sympathetic and parasympathetic output are reflexes triggered by visceral afferent nerves and the descending modulatory influence from the hypothalamus and brainstem. The baroreceptor reflex (baroreflex) is a critical feedback mechanism for buffering changes in arterial pressure. Inputs from the carotid sinus and baroreceptors in the aortic arch, activated by an increase in pulse pressure, reach the nucleus of the solitary tract, which triggers two responses that reduce blood pressure: activation of vagal output to the heart, thereby leading to decrease of the heart rate; and inhibition of sympathetic output to splanchnic and muscle blood vessels leading to a decrease of total peripheral resistance. Upon standing, unloading of the baroreceptors triggers sympathetically mediated vasoconstriction that limits venous pooling in the abdomen and lower limbs. Failure of this efferent baroreflex sympathetic vasoconstrictor response results in neurogenic orthostatic hypotension (Chapter 49). The primary causes are lesions that affect sympathoexcitatory neurons in the rostral ventrolateral medulla, preganglionic sympathetic neurons, and/or noradrenergic ganglion neurons or their

ABSTRACT

The autonomic nervous system is affected by many diseases of the central and peripheral nervous systems. Although this involvement is often mild or subclinical, autonomic involvement sometimes is prominent and a source of major disability. Autonomic dysfunction may manifest as autonomic failure or autonomic hyperactivity, may be generalized or focal, and may have a subacute, chronic progressive, or intermittent temporal profile. The presenting features include impairment of cardiovascular, gastrointestinal, urogenital, thermoregulatory, sudomotor, and pupillomotor function. The accurate diagnosis of the autonomic dysfunction is enhanced by imaging studies, physiologic tests, body fluid biomarkers, and structural studies of autonomic cutaneous innervation.

axons, and disorders that affect norepinephrine synthesis (e.g., dopamine-β-hydroxylase deficiency) or α1 receptor blockade.

The sympathetic output to the skin is critical for thermoregulatory sweating in response to heat and vasoconstriction in response to cold. Lesions that affect the descending pathway from the hypothalamus to the intermediolateral cell column, cholinergic sympathetic neurons or their axons, or that cause muscarinic receptor blockade impair sweating, thereby leading to anhidrosis and heat intolerance.

Cranial parasympathetic failure manifests with an impaired pupillary response to light as well as impaired lacrimation and salivation. Causes include involvement of individual cranial nerves, parasympathetic ganglion neurons, or muscarinic receptor blockade.

The vagus nerve is frequently affected in length-dependent neuropathies. Vagal impairment primarily affects upper gastrointestinal motility and beat-to-beat control of heart rate. The sacral preganglionic nucleus, which promotes contraction of the bladder detrusor or rectal sphincters, participates in reciprocal inhibitory interactions with the Onuf nucleus that is located at the S1-S3 levels and that innervate the external sphincter and pelvic floor. These interactions, which are controlled by descending inputs from the pons, allow coordination of bladder or rectal contraction and external sphincter relaxation. A neurogenic bladder (Chapter 115) can manifest with detrusor overactivity, detrusor-sphincter dyssynergia, or detrusor activity with urinary retention, depending on the level of the lesion.

Motility in the gut involves peristaltic reflexes that are mediated by the enteric nervous system under the excitatory parasympathetic and inhibitory sympathetic modulation. Disorders affecting enteric ganglia or their extrinsic control primarily result in constipation (Chapter 118) but are occasionally associated with diarrhea (Chapter 126) and fecal incontinence (Chapter 131).

Pathogenesis

Autonomic disorders, which can affect the sympathetic, parasympathetic, or enteric nervous systems, either in isolation or in various combinations, can be classified on the basis of their localization and underlying pathologic substrate (Table 386-1). The main causes of autonomic disorders include neurodegenerative synucleinopathies, autonomic ganglionopathies, small fiber peripheral neuropathies, and focal lesions.

Neurodegenerative synucleinopathies that may manifest with prominent progressive autonomic failure[7] include multiple system atrophy, Parkinson disease (Chapter 378), and dementia with Lewy bodies (Chapter 371). These conditions are characterized by the accumulation of abnormally misfolded α-synuclein aggregates that propagate in a prion-like fashion between neighboring cells, thereby leading to progressive disease in the central and peripheral nervous systems.

A second major group of disorders associated with generalized autonomic failure are the autoimmune ganglionopathies.[8] Damage to the autonomic ganglia, which are a major target of autoimmune disorders, produces subacute, generalized autonomic failure. The prototypical example is autoimmune autonomic ganglionopathy, which is caused by antibodies directed against ganglion-type nicotinic acetylcholine receptors and affects transmission at sympathetic, parasympathetic, and enteric ganglia.[9]

The third major group of disorders associated with autonomic failure are small fiber neuropathies[10] (Chapter 388), which affect unmyelinated and small myelinated axons from nociceptors as well as autonomic ganglionic neurons. Autonomic impairment is commonly associated with neuropathic pain and loss of sensation to pain and temperature. Some of these autonomic neuropathies are hereditary, such as hereditary transthyretin-related amyloidosis (hATTR) polyneuropathy (formerly known as familial amyloid polyneuropathy), which is due to mutations of the transthyretin (*TTR*) gene (Chapter 174). Less frequent examples are hereditary sensory and autonomic neuropathies (HSANs), such as HSAN type III (familial dysautonomia) associated with mutations of the *ELP1/IKBKAP* gene; sodium channelopathies such as those associated with variants in the genes encoding sodium channels $Na_V1.7$ (*SCN9A*); and Fabry disease associated with mutations of the *GLA* gene that encodes α-galactosidase (Chapter 192). Focal disorders affecting the central or peripheral nervous system may produce local autonomic manifestations.

CLINICAL MANIFESTATIONS

The classical clinical manifestations of autonomic disorders are related to autonomic failure, but other types of autonomic dysfunction may dominate the clinical picture.

TABLE 386-1 CLASSIFICATION OF AUTONOMIC DISORDERS

CENTRAL NERVOUS SYSTEM DISORDERS
Neurodegenerative disorders (synucleinopathies)
Multiple system atrophy
Parkinson disease
Dementia with Lewy bodies
Autoimmune encephalitis
Focal brain disorders
Traumatic brain injury
Insular stroke
Temporal lobe seizures
Hypothalamic disorders
Wernicke encephalopathy
Brainstem stroke
Syringobulbia
Focal spinal cord disorders
Spinal cord injury
Multiple sclerosis
Neuromyelitis optica
Syringomyelia
GANGLIONOPATHIES
Pure autonomic failure
Autoimmune ganglionopathies
Autoimmune autonomic ganglionopathy
Paraneoplastic ganglionopathy
Sjögren syndrome
PERIPHERAL NEUROPATHIES
Autoimmune neuropathies
Autoimmune sensory and autonomic neuropathy
Guillain-Barré syndrome
Lambert-Eaton myasthenic syndrome
Diabetic autonomic neuropathy
Generalized diabetic autonomic neuropathy
Treatment-induced neuropathy
Amyloid neuropathy
Light chain (AL) amyloidosis
Hereditary amyloid neuropathy including hATTR amyloidosis
Hereditary neuropathies
Hereditary sensory and autonomic neuropathies (HSANs)
Sodium channelopathies
Fabry disease
Metabolic neuropathies
Thiamine deficiency
Vitamin B_{12} deficiency
Toxic neuropathies
Alcohol
Chemotherapeutic agents (e.g., vincristine, taxanes, bortezomib)
Hydrocarbons, organic solvents
Infectious neuropathies
Human immunodeficiency virus
Chagas disease
Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2)
OUTPUT-SELECTIVE DISORDERS
Horner syndrome
Adie pupil
Harlequin syndrome
Trigemino-autonomic cephalalgia
Ross syndrome
Essential hyperhidrosis
Chronic idiopathic anhidrosis
Complex regional pain syndrome
ORTHOSTATIC INTOLERANCE WITHOUT AUTONOMIC FAILURE
Postural tachycardia syndrome
Reflex (vasovagal) syncope

Autonomic Failure

The most disabling manifestation of autonomic failure is orthostatic hypotension, defined as a sustained reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic blood pressure of at least 10 mm Hg, usually within the first 3 minutes of standing or a head-up tilt on a tilt table.[11] Orthostatic hypotension indicates volume depletion, impaired peripheral vasoconstriction, or both. Symptoms reflect hypoperfusion of the brain (lightheadedness, cognitive slowing, syncope), retina (blurry or dimmed vision), upper body

muscles ("coat hanger pain"), lungs (dyspnea owing to apical hypoperfusion), and, rarely, the heart (angina). These symptoms are typically more severe in the morning and worsen during exercise, after meals (postprandial hypotension) due to splanchnic vasodilation, upon exposure to heat (owing to skin vasodilation), and with prolonged bed rest that results in physical deconditioning. Patients with cognitive impairment may not accurately identify symptoms of organ hypoperfusion. Supine hypertension, defined as systolic blood pressure 140 mm Hg or higher and/or diastolic blood pressure 90 mm Hg or higher, measured after at least 5 minutes of rest in the supine position, occurs in about 50% of patients with neurogenic orthostatic hypotension (Chapter 64). Supine hypertension promotes overnight natriuresis, thereby causing intravascular volume depletion that predisposes to symptomatic orthostasis in the morning.

A second major manifestation of sympathetic failure is widespread anhidrosis, which produces heat intolerance that manifests with lightheadedness, fatigue, and facial flushing upon exposure to a hot environment. Anhidrosis in the feet and hands occurs in small fiber peripheral neuropathies, whereas patchy, non-length-dependent anhidrosis in the trunk and limbs occurs in autonomic ganglionopathies. Focal or regional anhidrosis is associated with compensatory hyperhidrosis, which occurs either adjacent or distant to areas of anhidrosis and leads patients to seek medical attention.

Cranial parasympathetic failure manifests as intolerance to light, dry eyes (xerophthalmia), and dry mouth (xerostomia) (Chapter 393). Upper gastrointestinal dysmotility (Chapter 122) manifests with dysphagia and delayed gastric emptying, thereby producing early satiety, anorexia, nausea, bloating, belching, postprandial vomiting, and pain (Chapter 122). Lower gastrointestinal dysmotility usually manifests with constipation and impaired defecation, but it also can occasionally cause diarrhea. Detrusor overactivity produces urinary urgency with or without incontinence, urinary frequency, and nocturia (Chapter 115). Reduced detrusor activity leads to incomplete bladder emptying, increased postvoid residual, and eventually urinary retention and overflow incontinence.

Orthostatic Intolerance without Autonomic Failure

A frequent cause of orthostatic intolerance is postural tachycardia syndrome (POTS; Chapter 49), which is a heterogeneous condition that is defined by a sustained heart rate increment of more than 30 beats per minute within 10 minutes of standing or head-up tilt, associated with symptoms of cerebral hypoperfusion (e.g., lightheadedness) and sympathetic activation (e.g., palpitations and chest pressure). The standing heart rate is typically greater than 120 beats per minute. Some patients have evidence of a mild autonomic neuropathy affecting the lower limbs. Other mechanisms include hypovolemia, venous pooling, cardiovascular deconditioning, and hyperadrenergic states, which may occur in combination.

Neurally mediated (reflex) syncope (Chapter 49) can be triggered by orthostatic stress as well as by visceral stimuli (e.g., deglutition, micturition, or defecation), cough, pain, and emotional states. It may be preceded by manifestations of sympathetic hyperactivity, such as pallor and diaphoresis. Rarely it may be due to carotid sinus hypersensitivity or a manifestation of glossopharyngeal neuralgia (Chapter 367).

Afferent Baroreflex Failure

Afferent baroreflex failure manifests with wide fluctuations of arterial pressure (Chapter 64). The main causes are prior neck radiation or bilateral neck surgery affecting the carotid sinus, familial dysautonomia (HSAN-III), Guillain-Barré syndrome (Chapter 388), and medullary lesions. Baroreflex failure can result in acute hypertensive crisis immediately following a lesion, but it most commonly manifests with fluctuating hypertension that may develop several months or years after surgical or radiation injury. The hypertensive surges are typically associated with tachycardia, diaphoresis, severe headache, and anxiety, thereby resembling a pheochromocytoma (Chapter 209). Patients may experience hypotension during sedation and sleep, or they may experience orthostatic hypotension in the setting of volume depletion or treatment with vasodilators or sympatholytic drugs. Less frequently, patients may have episodes of hypotension and bradycardia or episodes of orthostatic tachycardia.

Autonomic Hyperactivity

Autonomic hyperactivity, which is a life-threatening manifestation of some neurologic, iatrogenic, and toxic disorders,[12] typically manifests with excessive sympathetic output that leads to tachycardia, hypertension, diaphoresis, piloerection, and pupillary dilatation. Sympathoadrenal hyperactivity may lead to intracerebral hemorrhage (Chapter 377), hypertensive encephalopathy (Chapter 376), posterior reversible encephalopathy syndrome (Chapter 392), takotsubo cardiomyopathy (Chapter 47), pulmonary edema (Chapter 45), and supraventricular or ventricular arrhythmias (Chapters 50, 51, 52, and 53). Major causes include traumatic brain injury (Chapter 368), subarachnoid hemorrhage (Chapter 377), status epilepticus (Chapter 372), autoimmune encephalitis (Chapter 383), autonomic dysreflexia after spinal cord injury (Chapter 368), Guillain-Barré syndrome (Chapter 388), and severe emotional stress (Chapter 362). In some conditions, such as severe traumatic head injury (Chapter 368), tetanus (Chapter 271), malignant hyperthermia (Chapter 400), neuroleptic malignant syndrome (Chapter 402), and serotonin syndrome (Chapter 213), sympathetic hyperactivity is associated with hyperthermia, muscle rigidity, and myoclonus. In isolation, excessive parasympathetic activity is rare, except when temporal lobe seizures cause bradycardia, heart block, or asystole.

Sweating Disorders

Sweating disorders (sudomotor dysfunction) may be the sole manifestation of autonomic disorder.[13] Essential or primary generalized hyperhidrosis is typically most pronounced over the face, neck, and upper trunk. Secondary generalized hyperhidrosis is often associated with drugs or systemic illness. Primary focal hyperhidrosis affects palms, soles, axilla, and sometimes the craniofacial region; it may be exacerbated by anxiety, physical exertion, or heat exposure. Anhidrosis, which refers to the absence of sweating, may occur in central or peripheral autonomic disorders or as a side effect of drugs, most commonly anticholinergic agents. Sympathetic vasomotor and sudomotor dysfunction, which are associated with neuropathic pain, hypesthesia, and allodynia affecting one limb, is the typical manifestation of chronic regional pain syndrome (Chapter 388).

Cranial Autonomic Dysfunction

Cranial autonomic disorders reflect abnormalities in sympathetic outputs via the superior cervical ganglion or parasympathetic outputs via the ciliary, sphenopalatine, or other cranial ganglia. Horner syndrome (Chapter 392), which is a unilateral deficit of sympathetic innervation of the eye and face, results in miosis, mild ptosis, and facial anhidrosis (Chapter 392). It is an important clue to carotid artery dissection (Chapter 376), apical lung neoplasm (Pancoast syndrome; Chapter 177), cervical myelopathy (Chapter 369), or brainstem stroke (Chapters 375, 376 and 377). Hemifacial flushing or sweating in response to heat stress, emotion, or exercise, known as harlequin syndrome, indicates a contralateral sympathetic sudomotor deficit caused by a lesion that affects the superior cervical ganglion.

Lesions affecting the ciliary ganglion produce an Adie pupil (Chapter 392), which is an unreactive pupil that eventually develops a tonic response to light and accommodation. An Adie pupil may occur in isolation, in association with symmetrical or asymmetrical loss of muscle stretch reflexes (Holmes-Adie syndrome), or in Ross syndrome, which is a chronic autonomic disorder consisting of the triad of ipsilateral or bilateral tonic pupils, tendon hyporeflexia, and segmental body anhidrosis. Trigemino-autonomic cephalalgias, including cluster headache, are typically associated with ipsilateral miosis, conjunctival congestion, lacrimation, and rhinorrhea (Chapter 367).

Gustatory hyperhidrosis primarily affecting the face is triggered by hot or spicy foods. One example is Frey syndrome, which may develop after injury of the auriculotemporal nerve in the parotid region and reflects aberrant reinnervation of sweat glands by facial nerve branches destined to the salivary glands. Gustatory sweating may also occur in diabetic autonomic neuropathy (Chapter 210).

DIAGNOSIS

Clinical Evaluation

The mainstays of evaluation of patients with autonomic failure are a careful history as well as a general physical and neurologic examination to determine the type, distribution, and temporal profile of autonomic symptoms, as well as the presence of associated neurologic symptoms and signs (Fig. 386-1). The history should include a careful review of the patient's comorbid conditions and medication list (Table 386-2). Acute or subacute autonomic failure suggests an autoimmune ganglionopathy or a toxic cause. Chronic and progressive generalized autonomic failure suggests one of the neurodegenerative synucleinopathies, which are typically associated with and may be preceded by rapid eye movement (REM) sleep behavior disorder characterized by movements during sleep triggered by dreams (Chapter 374). Patients with suspected neurodegenerative disorders should be assessed for impaired olfaction (Chapter 395), which is an early symptom in Lewy body disorders but not of multiple system atrophy. Both patients and caregivers should be

instructed about recognition of inspiratory laryngeal stridor, which occurs in multiple system atrophy. The presence of sensory and autonomic symptoms suggests an autonomic neuropathy. Patchy, diffuse, or non-length-dependent sensory symptoms, and/or sensory ataxia suggests an immune ganglionopathy. A positive family history may be a clue to hereditary transthyretin amyloidosis (Chapter 174) or Fabry disease (Chapter 192).

The autonomic neurologic examination includes measurements of blood pressure and heart rate after 5 minutes of rest in the supine position and after 1 and 3 minutes of standing. A transient increase in heart rate during the first 15 to 30 seconds of standing is normal. In patients who have orthostatic hypotension, an increase in heart rate of less than 0.5 beats per minute for each mm Hg fall of systolic arterial pressure may indicate a neurogenic cause. The examination should also include assessment of the pupils (for size, symmetry, and reactivity with both bright and dim light), vasomotor signs, and sweat. Distal arteriolar vasoconstriction, which may manifest with cold hands and feet, can be seen in some patients with autonomic neuropathies or as "blue hands" in multiple system atrophy. Anhidrosis can be detected by palpation or a sense of resistance when sliding a tuning fork; hyperhidrosis is visualized by shining a bright light perpendicularly to the skin in a dimly lit room. Neurologic examination should include testing for parkinsonism, cerebellar ataxia, and both large and small fiber sensory loss (Chapter 366).

TABLE 386-2 DRUGS AFFECTING AUTONOMIC FUNCTION

SYMPTOM	DRUG (EXAMPLE)
Orthostatic hypotension	Diuretics Alpha-1 adrenoreceptor antagonists (e.g., terazosin) Calcium channel blockers Phosphodiesterase 4 inhibitors Nitrates Alpha-2 adrenoreceptor agonists (e.g., clonidine, tizanidine) Neuroleptics (e.g., clozapine)
Dry mouth Constipation Urinary retention	Anticholinergic drugs (e.g., trihexyphenidyl) Tricyclic antidepressants (e.g., amitriptyline)
Impaired sweating	Anticholinergic drugs (e.g., trihexyphenidyl) Tricyclic antidepressants (e.g., amitriptyline) Bupropion Antihistamines (e.g., doxepin, diphenhydramine, hydroxyzine) Neuroleptics (e.g., prochlorperazine) Carbonic anhydrase inhibitors (e.g., acetazolamide, topiramate) Central alpha-2 adrenoreceptor agonists (e.g., clonidine) Botulinum toxin
Excessive sweating	Serotonin reuptake inhibitors Opioids Acetylcholinesterase inhibitors (e.g., pyridostigmine)

Laboratory Evaluation

General laboratory tests in patients with autonomic failure should include a complete blood count; levels of serum glucose, hemoglobin A_{1c}, vitamin B_{12}, methylmalonic acid, thyroid-stimulating hormone, and creatinine, as well as serum and urine protein electrophoresis with immunofixation. Patients who have a subacute onset of autonomic symptoms should undergo testing for antibodies associated with autonomic failure or autonomic hyperactivity (Table 386-3).[14] Determination of forearm venous catecholamines after 30 minutes of supine rest and 10 minutes of standing may be helpful in some cases. Low basal norepinephrine levels indicate a disorder affecting autonomic ganglia or peripheral sympathetic nerves; normal supine norepinephrine levels suggest a central autonomic disorder, and low or undetectable noradrenaline levels associated with increased dopamine levels indicate a deficit of dopamine-β-hydroxylase, which normally transforms dopamine into norepinephrine.

Autonomic Function Tests

Autonomic laboratory evaluation is indicated to determine the presence, extent, and severity of autonomic failure; evaluate patients with orthostatic intolerance; and assess disease progression or therapeutic response. Sudomotor function tests include the thermoregulatory sweat test, which assesses the integrity of central and peripheral sudomotor pathways, as well as tests that assess peripheral innervation of the sweat glands, such as the quantitative sudomotor axon reflex test or the quantitative direct and indirect test of sudomotor function. Tests that assess vagal control of the sinus node (cardiovagal function) include the heart rate response to deep breathing (respiratory sinus

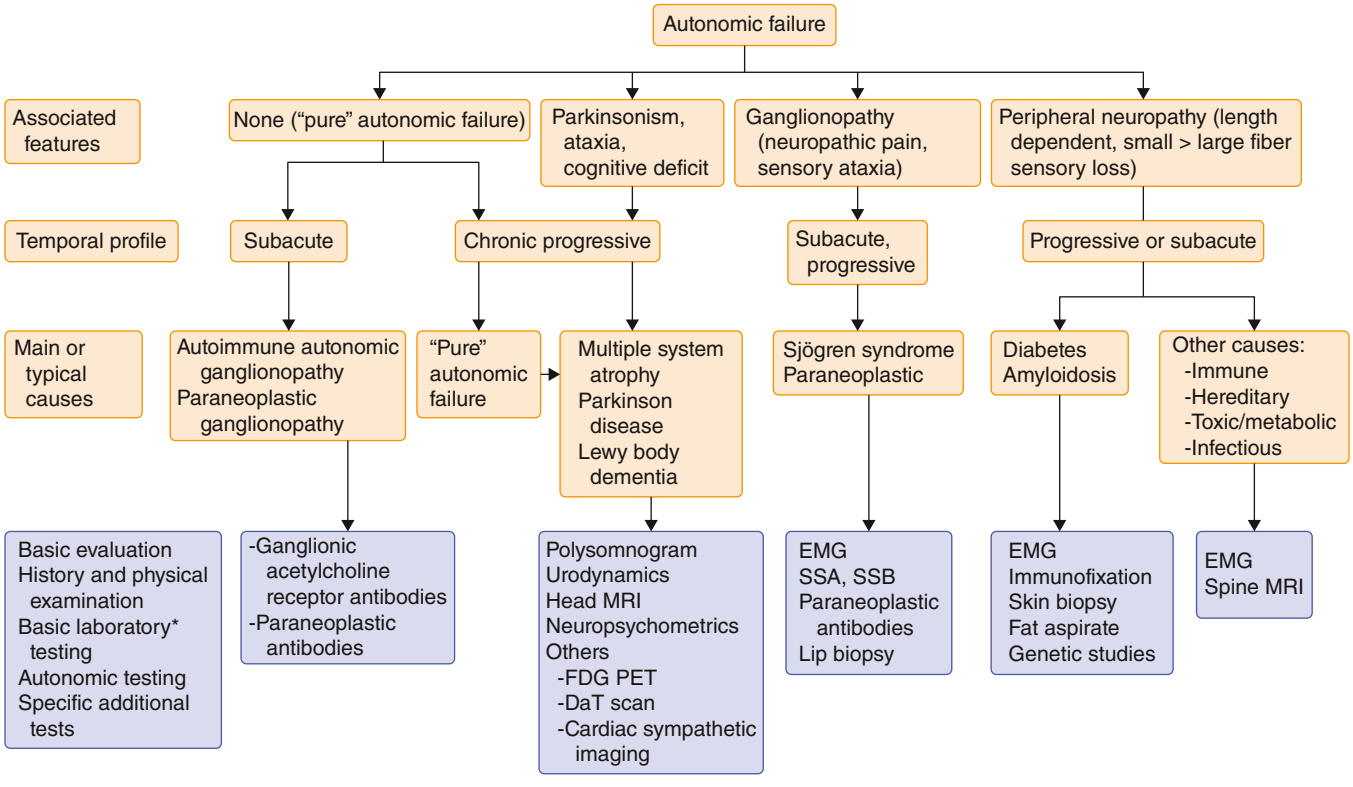

FIGURE 386-1. Approach to the diagnosis of a patient with signs or symptoms of autonomic failure. *Complete blood count, fasting blood glucose, vitamin B_{12}/methylmalonic acid, protein electrophoresis with immunofixation, plasma norepinephrine levels (supine and standing). TABLE 386-3 ANTIBODIES ASSOCIATED WITH AUTOIMMUNE AUTONOMIC DISORDERS

ANTIBODY	DISORDERS	ASSOCIATED CONDITION
DISORDERS ASSOCIATED WITH AUTONOMIC FAILURE		
Ganglionic AChR	Autoimmune autonomic ganglionopathy	Typically none May occur in association with other paraneoplastic autoantibodies
Hu (ANNA1)	Paraneoplastic autonomic neuropathy Intestinal pseudoobstruction	Small cell lung carcinoma, rarely thymoma
CRMP5	Paraneoplastic autonomic neuropathy	Small cell lung carcinoma, thymoma, renal cell carcinoma, thyroid carcinoma
SSA, SSB	Autoimmune sensory and autonomic ganglionopathy	Sjögren syndrome
P/Q VGCC	Lambert-Eaton myasthenic syndrome	Small cell lung carcinoma
DISORDERS ASSOCIATED WITH AUTONOMIC HYPERACTIVITY		
LGI	Limbic encephalitis	Typically, non-paraneoplastic, but <20% of cases may have small cell lung carcinoma, thymoma, or adenocarcinoma of the breast or prostate
CASPR2	Limbic encephalitis Morvan syndrome	Typically, non-paraneoplastic, but <20% of cases may have small cell lung carcinoma, thymoma, or adenocarcinoma of the breast or prostate
NMDAR	NMDAR encephalitis	Ovarian teratoma
DPPX	Encephalomyelitis with rigidity and myoclonus	Hematologic malignancies (<20% of patients)

AChR = acetylcholine receptor; CASPR2 = contactin-associated protein; DPPX = dipeptidyl peptidase X; LGI1 = leucine-rich glioma inhibited 1; NMDAR = N-methyl D-aspartate; SSA = Sjögren syndrome type A; SSB = Sjögren syndrome type B; VGCC = voltage-gated calcium channel.

arrhythmia) and the heart rate response to the Valsalva maneuver (Valsalva ratio). The beat-to-beat blood pressure profile during the Valsalva maneuver and the blood pressure response to head-up tilt indirectly assess the integrity of sympathetic vasomotor output in response to the baroreflex. The orthostatic stress in head-up tilt differs from that of active standing, as it does not involve contraction of calf muscles (which increases venous return). In patients who report typical orthostatic symptoms but do not have a fall in blood pressure within 3 minutes of standing, a more prolonged tilt-table test (Chapter 49) may detect delayed orthostatic hypotension, which can be seen with milder or earlier forms of autonomic failure.

Gastrointestinal motility studies assess gastric emptying, colonic transit, and defecatory function (Chapter 122). Urodynamic studies are necessary to assess bladder storage and emptying as well as detrusor sphincter dyssynergia (Chapter 115). Determination of postvoid residual volume is valuable to assess for impaired bladder emptying owing to impaired detrusor contractility.

Additional Tests in Specific Conditions

Electromyography and nerve conduction studies are indicated in all patients who are suspected of having peripheral autonomic nervous system dysfunction. Skin biopsy with assessment of intraepidermal nerve fiber density and immunocytochemical quantification of the innervation density of sweat gland and pilomotor nerves can be useful in the evaluation of small fiber neuropathy. Alpha-synuclein may also be detected in the cutaneous autonomic nerves in patients with or at risk for a synucleinopathy. Abdominal fat aspirate, skin biopsy, or sural nerve biopsy are indicated to evaluate for amyloidosis (Chapter 174); immunostaining, laser microdissection, and mass spectrometry–based proteomic analysis allow identification of the specific subtype of amyloid protein. Salivary gland or lip biopsy can support a diagnosis of Sjögren disease (Chapter 247). Genetic testing for transthyretin mutations of amyloidosis (Chapter 174) or determination of α-galactosidase for Fabry disease (Chapter 192) is indicated when these diseases are suspected.

Polysomnography is indicated in all patients who have progressive autonomic failure to detect REM sleep without atonia, which may manifest as REM sleep behavior disorder and which is often a premotor manifestation in the alpha-synucleinopathies (Chapter 374). Polysomnography may also detect laryngeal stridor in patients with multiple system atrophy before it manifests during wakefulness. Magnetic resonance imaging (MRI) is indicated in patients with a presentation suggestive of limbic encephalitis, a focal lesion, or a neurodegenerative disorder. Other imaging modalities, such as [^{18}F] fluorodeoxyglucose positron emission tomography, dopamine transporter imaging, or imaging of cardiac sympathetic innervation with [^{123}I] metaiodobenzylguanidine (MIBG) or 6-[^{18}F] fluorodopamine may help differentiate among different neurodegenerative disorders associated with autonomic failure.

TREATMENT

Regardless of the cause, the bothersome and sometimes life-threatening clinical manifestations of autonomic disorders require symptomatic treatment.

Orthostatic Hypotension

The goal of treatment for orthostatic hypotension is to improve the patient's symptoms rather than to achieve a target blood pressure.[15] Patient education about mechanisms and factors that worsen orthostatic hypotension is critical. The steps of management include correcting aggravating factors, nonpharmacologic measures, and pharmacologic therapies (Fig. 386-2). Patients who have asymptomatic neurogenic orthostatic hypotension usually require only education and nonpharmacologic measures.

Drugs that exacerbate orthostatic hypotension (see Table 386-2) should be reduced or discontinued if possible. Levodopa or dopaminergic agonists used to treat the Parkinsonism associated with the central synucleinopathies may also lower blood pressure, and their doses should be adjusted if possible.

Management of orthostatic hypotension requires lifestyle and dietary modifications.[16] Patients should be instructed to change positions gradually, briefly sit before standing, avoid Valsalva-like maneuvers, and use a urinal or urinate in the sitting position. They should also avoid exposure to hot and humid environments that cause vasodilatation. Patients should not stop exercising because of the adverse effects of cardiovascular deconditioning, but exercise is preferred in the recumbent or seated position or in a swimming pool.

Many patients have postprandial hypotension within 2 hours after a meal because of insulin-triggered splanchnic vasodilation, so patients should be instructed to eat smaller, more frequent meals that are low in carbohydrates. Alcohol, which is a powerful vasodilator, should be reserved for the evening, prior to bedtime. Fluid intake should be 2 to 2.5 L of water per day, and patients should increase their salt intake,[A1] such as by adding 1 to 2 teaspoons of salt to a healthy diet. Salt tablets (e.g., 0.5 g or 1.0 g tablets) can be used but may cause abdominal discomfort.

As a rescue measure for acute symptoms, bolus water drinking (0.5 L, 16 oz) produces a rapid increase in blood pressure owing to a reflex sympathoexcitatory response, presumably triggered by portal osmoreceptors. This pressor response occurs within 5 to 10 minutes and peaks in about 30 minutes, and it may persist for hours. Other physical countermaneuvers (e.g., leg crossing, standing on tiptoes, stooping, squatting, and buttock clenching) can help maintain blood pressure and reduce orthostatic symptoms during daily activities. High-waist stockings that produce at least 15 to 20 mm Hg compression or an abdominal binder can reduce venous pooling and thereby increase venous return and blood pressure.

When these interventions fail, pharmacologic strategies, which are aimed to expand intravascular volume and promote vasoconstriction, should be introduced (Table 386-4).[17] Stepwise pharmacologic treatment usually begins with low-dose fludrocortisone (0.1 mg/day).[A2] This long-acting synthetic mineralocorticoid, which increases renal sodium and water re-absorption, thereby expanding intravascular volume, usually requires at least 7 days of treatment to exert significant clinical effect. Midodrine (5 to 10 mg three times a day) is an oral prodrug converted peripherally into the active metabolite desglymidodrine, a selective α_1-adrenoceptor agonist that elicits arteriolar and venous constriction; it is an effective treatment for symptomatic orthostatic hypotension.[A3,A4] Droxidopa (100 to 600 mg three times a day), which is an oral synthetic amino acid that is decarboxylated to norepinephrine by the enzyme aromatic amino acid decarboxylase in the remaining sympathetic postganglionic terminals and in non-neuronal tissues, improves neurogenic orthostatic hypotension.[A5] Midodrine or droxidopa should be taken before getting out of bed, before lunch, and no later than 3 to 4 hours before bedtime to avoid supine hypertension. Norepinephrine reuptake inhibitors, such as atomoxetine (10 to 18 mg, twice a day), increase norepinephrine availability at the neurovascular junction and may be effective in patients who have preserved peripheral sympathetic function, as occurs in multiple system atrophy. Pyridostigmine (30 to 60 mg two to three times daily) is an inhibitor of cholinesterase; it potentiates cholinergic neurotransmission in autonomic ganglia and may increase sympathetic output "on demand" upon standing, without the risk of supine hypertension.

Other drugs can be used as adjunctive treatment in specific conditions (Fig. 386-2). The α-glucosidase inhibitor acarbose (50 to 100 mg before meals), which decreases gastrointestinal absorption of glucose and release of the vasodilator insulin, is useful to treat postprandial hypotension. The somatostatin analog octreotide (0.2 to 0.4 μg/kg, subcutaneously) induces splanchnic vasoconstriction and is very effective to attenuate postprandial hypotension. In patients who have anemia of chronic disease (Chapter 144), treatment with erythropoietin increases standing blood pressure and improves orthostatic tolerance.

Neurogenic supine hypertension poses a therapeutic challenge in patients who have orthostatic hypotension. During daytime, avoiding the supine position is the best treatment. During the night, tilting the head of the bed to achieve a 30- to 45-degree angle (reverse Trendelenburg position) lowers blood pressure and prevents the nocturnal polyuria and natriuresis that worsen orthostatic hypotension the next morning. Eating high-glycemic carbohydrate snacks or drinking a glass of wine right before going to bed also can decrease supine nocturnal hypertension. In patients who have prolonged and severe supine hypertension, short-acting drugs, such as captopril (25 mg), losartan (50 mg), nifedipine (1 to 2 mg), amlodipine (2.5 to 5 mg), or a nitroglycerine patch (0.1 mg), can be considered. Because these drugs increase the risk of hypotension and falls upon standing up from recumbency (e.g., to urinate), the use of a urinal or bedside commode should be encouraged.

Other Manifestations of Autonomic Failure

The care of patients with severe gastrointestinal or urologic symptoms requires referral to a specialist. Treatment of constipation (Chapter 118) includes increased water and fiber intake, bulking agents (e.g., psyllium), osmotic laxatives (e.g., polyethylene glycol and magnesium citrate), emollients (e.g., docusate), and gastrointestinal tract stimulants (e.g., cascara). More recently approved novel therapies include the guanylate cyclase C activator, linaclotide, and the chloride channel type 2 activator, lubiprostone.

Potential treatments of overactive bladder (Chapter 115) include antimuscarinic drugs (e.g., oxybutynin, tolterodine, trospium, darifenacin, solifenacin fesoterodine) or the β_3 receptor agonist mirabegron. Patients with detrusor hypoactivity and large (>100 mL) postvoid residual should practice intermittent self-catheterization. Erectile dysfunction (Chapter 216) is typically managed with oral phosphodiesterase 5 inhibitors, such as sildenafil, tadalafil, and vardenafil—all of which may worsen orthostatic hypotension—or with local treatment.

Hyperhidrosis

Initial treatment for palmar hyperhidrosis begins with tap water iontophoresis, which blocks the sweat ducts at the stratum corneum. Endoscopic transthoracic sympathotomy or sympathectomy can produce long-term benefit but may lead to compensatory hyperhidrosis at other sites. Intradermal botulinum toxin injections can be used for palmar or axillary hyperhidrosis and for gustatory sweating. Topical antiperspirants are the initial treatment for generalized hyperhidrosis. Pharmacologic treatment includes anticholinergic drugs such as glycopyrrolate (1 to 2 mg one to three times daily), which typically produces dry mouth; topiramate (beginning at 25 mg twice daily); and clonidine (0.1 mg three times daily).

SPECIFIC AUTONOMIC DISORDERS

NEURODEGENERATIVE SYNUCLEINOPATHIES

In synucleinopathies, slowly progressive generalized failure may occur either in isolation or in association with different motor and cognitive manifestations.[18] Pure autonomic failure is a sporadic, gradually progressive disorder of adult onset primarily characterized by orthostatic hypotension, in many cases associated with progressive loss of sweating, constipation, bladder disturbances and erectile dysfunction. Approximately one third have or may eventually develop multiple system atrophy or a Lewy body disorder.

Multiple system atrophy is characterized by prominent autonomic failure associated with Parkinsonism, cerebellar ataxia, or both (Chapters 378 and 379). The pathologic hallmark of multiple system atrophy is the accumulation α-synuclein containing glial cytoplasmic inclusions and loss of neurons in the striatum, substantia nigra, cerebellum, pons, and other brain regions. The prominent involvement of brainstem areas critical for cardiovascular control, micturition, and respiration explains the early and severe orthostatic hypotension, neurogenic bladder, and respiratory complications that characterize multiple system atrophy. Early and severe orthostatic hypotension and urinary retention with large postvoid residual (>100 mL) and incontinence typically differentiates this multiple system atrophy from Lewy body disorders. Laryngeal stridor is a typical manifestation, and its early development predicts shorter survival. A thermoregulatory sweat test typically shows global anhidrosis. Normal supine plasma norepinephrine levels and preserved cardiac sympathetic innervation on cardiac imaging reflect a relative preservation of autonomic ganglia at early disease stages. Survival in multiple system atrophy is poor, with a median survival from onset to death ranging from 6 to 10 years.

Autonomic failure in Parkinson disease and dementia with Lewy bodies reflects accumulation of α-synuclein in neurons and axons of the sympathetic, parasympathetic, and enteric ganglia. The pathologic hallmark of these disorders is accumulation of α-synuclein containing Lewy bodies and Lewy neurites.

In Parkinson disease (Chapter 378), involvement of the enteric nervous system typically occurs before that of the central nervous system and precedes the motor manifestations, thereby suggesting that Lewy neuropathology extends from the peripheral autonomic to the central nervous system. Autonomic manifestations, such as constipation, may precede the development of motor symptoms by over two decades. Impaired gastric emptying may contribute to variable absorption of levodopa and motor fluctuations. Orthostatic hypotension occurs in 50% of cases, may be detected early in the course of the disease, and may be aggravated by dopaminergic agonists. Urinary symptoms, which affect up to 85% of patients, reflect detrusor overactivity. Patients may be intolerant to heat or cold and may have intermittent episodes of hyperhidrosis, which more frequently occur during "off" periods in patients with motor fluctuations. Symptoms may be ameliorated temporarily by adjusting anti-Parkinsonism medication, and the prognosis is determined by the progression of the underlying disease.

Lewy body dementia is characterized by progressive dysfunction in attention and executive tasks, accompanied by visual processing deficits, fluctuating cognition, recurrent visual hallucinations, REM sleep behavior disorder, and Parkinsonism (Chapter 371). Autonomic dysfunction, neuroleptic sensitivity, postural instability, repeated falls, and neuropsychiatric manifestations are supportive clinical features. In Lewy body disorders, autonomic manifestations are primarily due to involvement of peripheral autonomic ganglia, as reflected by low supine plasma norepinephrine and cardiac sympathetic denervation on cardiac imaging. No specific treatments are available, and the prognosis is poor (Chapter 371), usually with rapid progression of symptoms and death within 5 to 7 years.

AUTOIMMUNE AUTONOMIC DISORDERS

Several autoimmune disorders may manifest with either autonomic failure or autonomic hyperactivity. Recognition of these disorders is critical because they may respond to immunomodulatory therapy, including high-dose corticosteroids, intravenous immunoglobulin or plasma exchange, and, in some cases, mycophenolate mofetil, cyclophosphamide, or rituximab.

Autoimmune autonomic ganglionopathy is an important cause of subacute panautonomic failure. Orthostatic hypotension and constipation occur in 70% of patients. Prominent cholinergic failure, manifested by dry mouth, dry eyes, impaired pupil responses, and urinary retention, is a typical feature. About 50% of patients have ganglionic acetylcholine receptor antibodies, whose levels correlate with severity of the disease; levels greater than 1.0 nmol/L are fairly specific. Intermediate levels of ganglionic acetylcholine receptor antibodies (0.1 to 1.0 nmol/L) can be associated with limited forms of autonomic failure, such as gastrointestinal dysmotility (including chronic intestinal pseudo-obstruction). Low titers are found in some cases of idiopathic anhidrosis, which may respond to corticosteroids under expert supervision.

Paraneoplastic antibodies (Chapter 164) can be associated with autonomic or enteric neuropathy. Small cell lung cancer (Chapter 177), which is the most commonly associated tumor, is especially associated with ANNA-1 (anti-Hu) and CRMP5 antibodies. Among patients with anti-Hu antibody, 18% present with an autonomic neuropathy, and 12% may initially present solely with enteric neuropathy.

Primary Sjögren syndrome[19] (Chapter 247) is characterized by sicca symptoms (dry mouth and dry eyes) and may manifest with sensory ganglionopathy or small fiber neuropathy. More than half of patients with neuropathy report symptoms of autonomic dysfunction. The diagnosis may be confirmed by the presence of SSA and SSB antibodies and/or lymphocyte infiltrates in salivary gland biopsy. Treatment is largely symptomatic, and prognosis depends on the response to treatment of Sjögren syndrome.

Seronegative idiopathic subacute autonomic and sensory neuropathy disorder is characterized by subacute onset of autonomic failure associated with prominent sensory manifestations. Symptoms include orthostatic hypotension, gastrointestinal dysmotility, neuropathic pain, and sensory ataxia with objective evidence of small or large fiber sensory neuropathy. MRI of the spinal cord may reveal increased T2 signal in the posterior columns. Lambert-Eaton myasthenic syndrome (Chapter 390), which is a neuromuscular junction disorder due to antibodies directed against the P/Q type voltage-gated calcium channel, results in impaired release of acetylcholine at both the neuromuscular junction and autonomic synapses. It manifests with proximal weakness, fatigability,

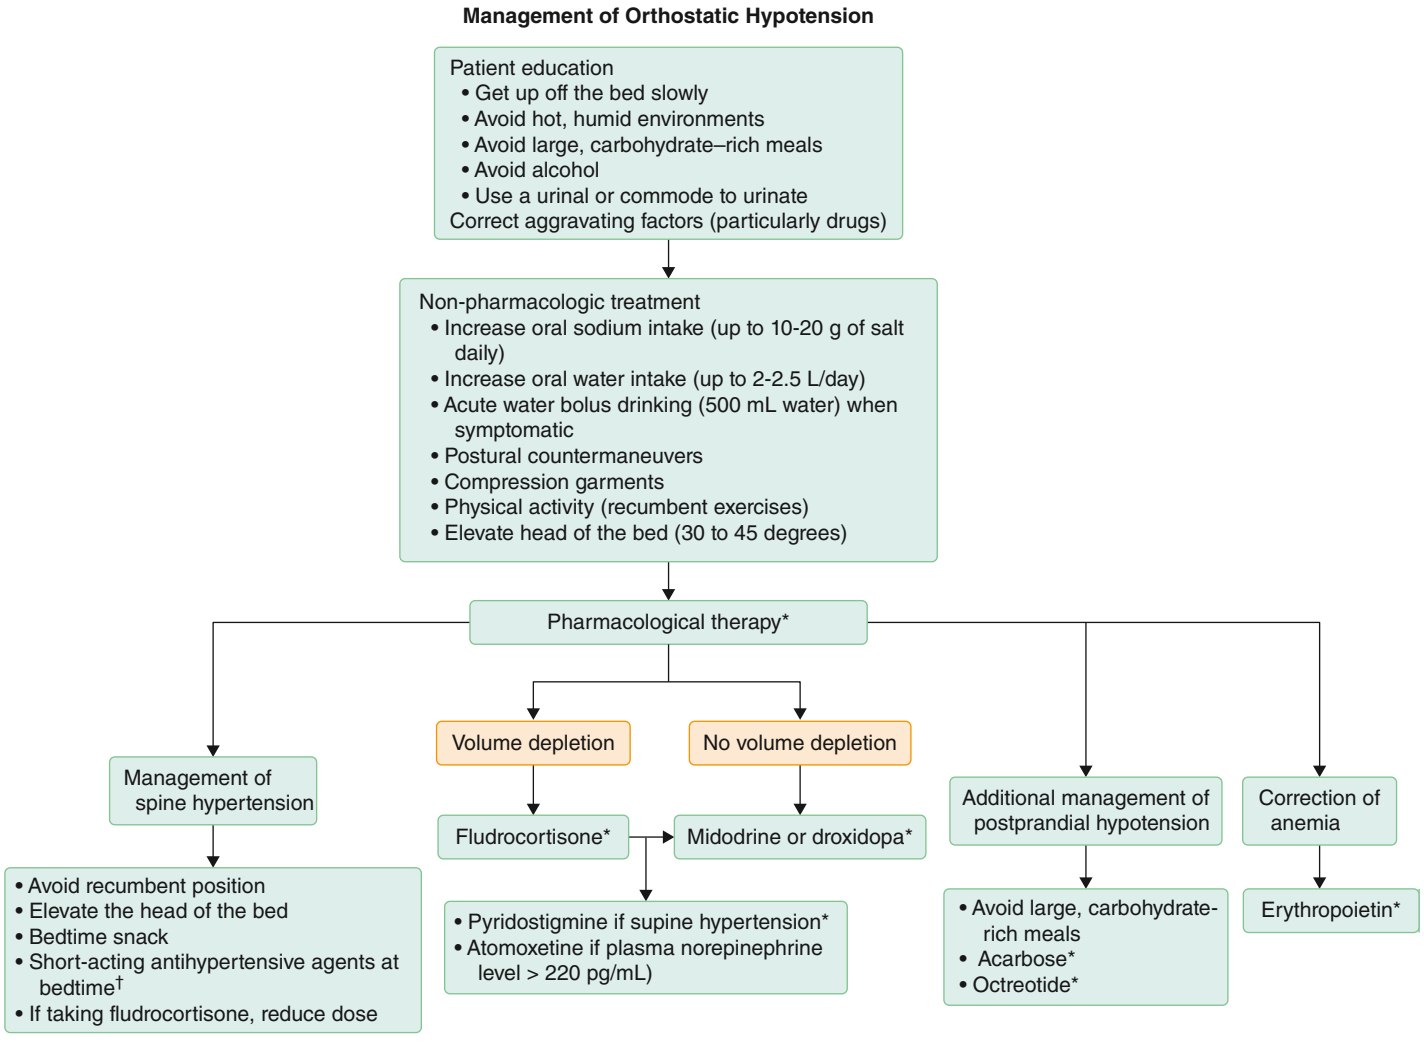

FIGURE 386-2. Approach to the management of orthostatic hypotension. *See Table 386-4 for drug doses. †See text for drugs and doses.

TABLE 386-4 DRUG MANAGEMENT OF ORTHOSTATIC HYPOTENSION

DRUG	DOSE	SIDE EFFECTS	COMMENTS
Fludrocortisone	0.1-0.2 mg orally daily	Supine hypertension, hypokalemia, ankle edema	Potential nephrotoxic effect, left ventricular hypertrophy
Midodrine	5-10 mg orally three times daily	Piloerection Scalp itching Urinary retention Supine hypertension	Take before getting out of bed, before lunch, and no later than 3-4 hr before bedtime
Droxidopa	100-600 mg orally three times daily	Supine hypertension	Take before getting out of bed, before lunch, and no later than 3-4 hr before bedtime
Pyridostigmine	30-60 mg orally three times daily	Bradycardia, abdominal cramps, diarrhea, sialorrhea, urinary incontinence	Increase standing blood pressure without risk of orthostatic hypotension Can be administered together with each dose of midodrine
Atomoxetine	10-18 mg orally twice daily	Insomnia, irritability decreased appetite	May be more helpful in patient with preserved sympathetic terminals
Acarbose	50-100 mg orally before meals		Adjuvant treatment of postprandial hypotension
Octreotide	0.2-0.4 mcg/kg, SQ	Nausea, abdominal pain	Adjuvant treatment of postprandial hypotension
Erythropoietin	25-75 U/kg SQ three times a week until hematocrit normalizes, then 25 U/kg three times weekly	Hypertension	Treatment of anemia of chronic disease worsens hypotension; iron supplementation also may be required

SQ = subcutaneous.

and areflexia (Chapter 390). Autonomic symptoms include dry mouth, constipation, and erectile dysfunction. This disorder is typically associated with small cell lung carcinoma. Treatment focuses on the underlying malignancy, but the prognosis is poor.

In Guillain-Barré syndrome (Chapter 388), up to two thirds of patients may have autonomic dysfunction, which can be life-threatening. Manifestations include labile blood pressure and heart rate, paralytic ileus, and urinary retention. These manifestations resolve as the neuropathy resolves.

Several autoimmune disorders affecting the central nervous system may be associated with autonomic hyperactivity.[20] For example, autonomic encephalitis due to antibodies against the voltage-gated potassium channel complex proteins LGI1 (leucine-rich glioma inactivated protein 1) or CASPR2 (contactin-associated protein–like 2) may manifest with episodes of hyperhidrosis, tachycardia, labile blood pressure, and hypersalivation. In N-methyl-D-aspartate (NMDA) receptor encephalitis (Chapter 383), the prominent psychiatric, cognitive, and motor manifestations may be accompanied by tachyarrhythmias, labile blood pressure, and central hypoventilation. Antibodies against dipeptidyl peptidase X (DPPX) produce a disorder characterized by profuse diarrhea and weight loss, followed by confusion, psychosis, myoclonus, exaggerated startle responses, and, in some cases, cardiac arrhythmias. Neuromyelitis optica spectrum disorder (Chapter 392), which is associated with aquaporin 4 antibodies, may manifest with intractable hiccups and vomiting, owing to involvement of the area postrema, and with hypothalamic dysfunction, including the syndrome of inappropriate secretion of antidiuretic hormone and narcolepsy. In these autoimmune disorders, the prognosis depends on the progression of the underlying disease.

PERIPHERAL AUTONOMIC NEUROPATHIES

Autonomic dysfunction may be a prominent manifestation of a variety of peripheral neuropathies.

DIABETES

Autonomic neuropathies in diabetes (Chapter 210) include generalized autonomic neuropathy, treatment-induced neuropathy, autonomic neuropathy of prediabetes, and hypoglycemia-associated autonomic impairment.[21] Generalized autonomic neuropathy typically occurs in the setting of a generalized diabetic polyneuropathy but may occur in isolation. About 65% of patients develop impaired cardiac vagal function, manifested by reduced heart rate variability on autonomic testing, and about 25% develop orthostatic hypotension. Rigorous glycemic control can delay the appearance and slow the progression of neuropathy in type 1 diabetes[A6] Cardiovascular autonomic neuropathy in diabetes is associated with a significant morbidity and mortality, ranging from 27 to 56% over 5 to 10 years.

Gastrointestinal tract dysfunction in diabetic autonomic neuropathy reflects abnormalities in the enteric nervous system, the parasympathetic vagal and pelvic nerves, and the sympathetic mesenteric nerves, in various combinations.[22] Hyperglycemia may also slow gastric emptying. Gastroparesis (Chapter 122) may occur in 20 to 50% of patients, and constipation may be found in up to 50% of patients, frequently associated with diarrhea. Fecal incontinence, due to anal sphincter incompetence or reduced rectal sensation, may be exacerbated by diarrhea. Voiding dysfunction occurs in up to 80% patients with diabetic autonomic neuropathy. Erectile failure, which is present in up to 75% of men with diabetes, may be the earliest symptom of autonomic neuropathy. Ejaculatory failure may precede the appearance of erectile dysfunction. Impaired bladder neck closure during ejaculation results in retrograde ejaculation. Impaired vaginal lubrication may also occur in diabetic patients. Sweating is typically impaired in a length-dependent fashion.

Treatment-induced neuropathy should be considered in patients who have diabetes and who present with the sudden onset of neuropathic pain and autonomic dysfunction. This reversible diabetic peripheral neuropathy is associated with rapidly instituted glycemic control, typically in patients who had a high pretreatment hemoglobin A_{1c} level, and may occur in patients with type 1 or type 2 diabetes treated with oral hypoglycemic agents or insulin. Symptoms of autonomic dysfunction, particularly orthostatic intolerance and gastrointestinal manifestations, are particularly prominent in patients with type 1 diabetes. Autonomic symptoms and test results tend to improve over time.

AMYLOIDOSIS

Peripheral autonomic neuropathy is a prominent feature of both primary (AL) and hereditary ATTR amyloidosis[23,24] (Chapter 174). Amyloid neuropathy results from abnormal deposition of insoluble beta-fibrillar proteins in the epi-, peri-, and endoneurium; the perineuronal tissues; and the neural vasculature.

Peripheral neuropathy, which is present in at least 20% of patients with AL amyloidosis, may be the presenting feature or an incidental finding. The most common manifestations are a length-dependent polyneuropathy associated with neuropathic pain and generalized autonomic failure.

Familial amyloid polyneuropathy is due to mutations of the transthyretin (*TTR*) gene on chromosome 18, most commonly a substitution of methionine for valine at position 30 (Val30Met). Hereditary ATTR amyloidosis with neuropathy is a progressive, debilitating, multisystem, life-threatening disease that typically has an insidious onset in the third to fifth decade. Autonomic manifestations are prominent and may be the presenting feature of the neuropathy.

The major diagnostic tools to diagnose amyloidosis are serum and urine immunoelectrophoresis; evaluation for cardiac amyloidosis (e.g., echocardiogram, cardiac MRI, and scintigraphy); subcutaneous fat aspirate, bone marrow biopsy, or lip biopsy with Congo red staining; amyloid typing with tissue mass spectrometry or immunocytochemistry; and germline DNA testing.[25] Cardiac biomarkers, such as troponin and N-terminal fragment of brain natriuretic peptide, are used for staging.

TREATMENT AND PROGNOSIS

For AL amyloidosis, high-dose chemotherapy followed by autologous stem cell transplant is usually the treatment of choice in eligible patients (Chapter 174). The addition of bortezomib to melphalan/prednisone regimens significantly improves both progression-free and overall survival in AL amyloidosis.[A7] Daratumumab, which is a monoclonal antibody directed to the CD38 antigen, is approved for treatment of multiple myeloma and is being studied in newly diagnosed patients with AL amyloidosis. Prognosis is linked to the outcome of treatment for the underlying disease.

For ATTR amyloidosis, effective treatments are now available for both the cardiac and neuropathic complications. Options to slow the progression of polyneuropathy include the small interfering RNA patisiran (30 mg intravenously every 3 weeks; see Chapter 174),[A8] diflunisal (a nonsteroidal anti-inflammatory agent at 250 mg twice daily), and the antisense nucleotide inotersen (284 mg subcutaneously weekly).[A9] Tafamidis (80 mg daily) slows the progress of cardiac disease and reduces all-cause mortality in patients with variant ATTR amyloidosis.[A10] The major determinant of prognosis in patients with amyloidosis is the extent of cardiac involvement, which portends a 1-year mortality of 40% and a median survival ranging from 22.2 to 96.5 months.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHIES

Many mutations affecting proteins critical for development and survival of sensory and autonomic nerves cause hereditary sensory and autonomic neuropathies. These conditions, which present in infancy and childhood, are autosomal recessive disorders with abnormal development of primary sensory nerves.

Variants in the genes encoding sodium channels selectively expressed in nociceptive afferents and autonomic axons have been linked to small fiber neuropathy associated with autonomic dysfunction. Gain-in-function variants in the genes encoding sodium channels $Na_v1.7$ (*SCN9A*), Nav 1.8(*SCNA10*), and $Na_v1.9$ (*SCN11A*) that are expressed in nociceptive neurons have been found in some patients with small fiber neuropathy. Gain-in-function *SCN9A* mutations have been linked to familial paroxysmal pain syndromes, including familial erythromelalgia, whereas loss-of-function *SCN9A* mutations have been linked to insensitivity to pain. Autonomic features, which include dry mouth and eyes, reduced urinary sensation, urinary hesitancy, orthostatic dizziness, hyperhidrosis, palpitations, and alternating constipation and diarrhea, can be present in some patients who harbor the *SCN9A* mutations affecting $Na_v1.7$ channel function. Similar, although less prominent, autonomic manifestations have been reported in patients harboring *SCN10A* and *SCN11A* mutations. No treatments are currently available.

Fabry disease, which is an X-linked, recessively inherited disorder associated with deficiency of alpha-galactosidase A (Chapter 192), manifests with a painful peripheral neuropathy associated with pain crises, hypohidrosis, and gastrointestinal symptoms. Typical features include angiokeratomas in the lower abdomen and genital regions; corneal dystrophy; hearing loss; vertigo; and renal, coronary, and cerebrovascular disease. Enzyme replacement therapy (agalsidase) and in some cases adjuvant treatment with migalastat may reduce complications, particularly when used early in the course of the disease.

METABOLIC, TOXIC, AND INFECTIOUS CAUSES

Several metabolic, toxic, and infectious neuropathies may manifest with prominent autonomic features. Thiamine deficiency (Chapter 199), like alcoholic

neuropathy (Chapter 384), may manifest with early involvement of the vagus nerve, followed by late development of orthostatic hypotension. Vitamin B_{12} deficiency may occasionally be associated with orthostatic hypotension. Replacement of vitamin deficiencies is important. Alcoholic neuropathy is usually permanent and will progress if drinking continues.

Toxins that may produce peripheral autonomic neuropathy include chemotherapeutic agents, such as vinca alkaloids, platinum derivatives, taxanes, thalidomide, lenalidomide, and bortezomib. Industrial and environmental toxins potentially causing autonomic neuropathy include organic solvents, arsenic, mercury, acrylamide, and thallium (Chapter 20). Organophosphate poisoning (Chapter 96) produces life-threatening cholinergic muscarinic hyperactivity with bradycardia and increased lacrimal, salivary, and bronchial secretions, owing to their inhibition of acetylcholinesterase. Botulinum toxin (Chapter 271) prevents the release of acetylcholine, thereby producing neuromuscular weakness, dilated and unreactive pupils, dry mouth, anhidrosis, constipation, and urinary retention. In contrast, tetanus toxin (Chapter 271) prevents release of γ-aminobutyric acid and glycine in the brain stem and spinal cord, thereby leading to sympathetic hyperactivity that results in tachycardia, hypertension, fever, and profuse sweating.

Some infectious neuropathies may also affect autonomic function. Human immunodeficiency virus (HIV) infections (Chapter 359) may be associated with orthostatic hypotension, tachycardia, cardiac conduction defects, diarrhea, and genitourinary dysfunction. Chagas disease (Chapter 318) affects enteric ganglia, thereby producing megaesophagus and megacolon, as well as causing a cardiomyopathy. Leprosy (Chapter 301) may be associated with focal anhidrosis in areas of hypopigmented and hypoesthesic skin. Autonomic dysfunction has also been observed in some survivors of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection (Chapter 336).[26]

FOCAL CENTRAL NERVOUS SYSTEM DISORDERS

Autonomic dysfunction may be a prominent feature of focal lesions of the brain or spinal cord. Strokes involving the insula (Chapter 376) can be complicated with cardiac arrhythmia, myocardial injury, or, in rare cases, contralateral hyperhidrosis. Temporal lobe seizures (Chapter 372) may manifest with ictal tachycardia or bradycardia (including asystole), ipsilateral piloerection or hypersalivation, episodic abdominal pain and vomiting, and ictal apnea. Paroxysmal hypothermia with hyperhidrosis is a rare hypothalamic disorder characterized by episodic hypothermia associated with excessive sweating, flushing or pallor, bradycardia, weakness, ataxia, and confusion. It may rarely associate with agenesis of the corpus callosum (Shapiro syndrome), but in most cases the cause is unknown. Wernicke encephalopathy (Chapter 384) may be associated with hypothermia. Strokes or neoplasms involving the medulla may manifest with orthostatic hypotension, paroxysmal hypertension, cardiac arrhythmias, vomiting, and respiratory dysfunction, in several combinations.

Disorders of the spinal cord, such as multiple sclerosis (Chapter 380), neuromyelitis optica (Chapter 392), syringomyelia (Chapter 385), and spinal cord injury (Chapter 368), may affect autonomic function. The manifestations and severity of autonomic dysfunction depend on the spinal segment involved, extent of the lesion, and time since the acute injury. Neurogenic bladder, bowel, and sexual dysfunction are a frequent feature. Acute spinal cord injury results in severe hypotension and areflexic bladder, ileus, and impaired response to thermal stimuli. Autonomic dysreflexia, which occurs in patients with spinal cord lesions above the T5 spinal level, consists of reflex sympathoexcitation characterized by severe hypertension, headache, flushing, piloerection, sweating about the level of the lesion, and bradycardia. These episodes can be triggered by bladder distension, fecal impaction, or nociceptive stimuli below the lesion and may result in hypertensive encephalopathy, cerebral or retinal hemorrhage, and cardiac arrhythmias.

REGIONAL SYMPATHETIC DYSFUNCTION

Regional sympathetic dysfunction can be a manifestation of complex regional pain syndrome. This condition, which is often a result of injury, is characterized by pain, hyperalgesia (an exaggerated response to normally painful stimuli), and allodynia (pain in response to stimuli that normally are not painful, such as light touch). These painful symptoms are accompanied by varying combinations of motor, sensory, autonomic, and trophic features. Complex regional pain syndrome can be subdivided into two clinical subtypes: type I, the more common, in which the intensity, duration, and extension of pain are out of proportion to an originally minor or inapparent injury; and type 2, which develops after major nerve damage. The warm subtype of autonomic features is characterized by a warm, red, edematous, and sweaty extremity, whereas the cold subtype manifests as a cold, blue extremity. Most cases are in the upper limbs, and about 80% of cases are in females.[27] The underlying pathobiology is unclear. The sudomotor findings can range from regional hyperhidrosis to anhidrosis. Local dystrophic changes include dry atrophic skin, sparse or coarse hair, brittle nails, and osteopenia.

Early in the syndrome, mobilization of the affected limb may be important, but the evidence base in support of any intervention is limited.[28] Analgesic medications and regional anesthesia may help facilitate physical therapy, which can be helpful.[A11] Improvement has been reported in small studies with interventions such as bisphosphonates (e.g., alendronate), ketamine infusions, corticosteroids (e.g., prednisone or methylprednisolone), epidural clonidine, intrathecal baclofen, and epidural spinal cord stimulation under expert supervision. However, the level of evidence for these interventions is low, and none of these treatments are well established. Most patients improve within 12 months, but a significant proportion of patients have persisting symptoms, ongoing disability, and impaired quality of life.

387 AMYOTROPHIC LATERAL SCLEROSIS AND OTHER MOTOR NEURON DISEASES

PAMELA J. SHAW AND MERIT E. CUDKOWICZ

DEFINITION

The motor neuron diseases (Table 387-1) are a heterogeneous group of disorders in which selective loss of function of upper motor neurons, lower motor neurons, or both results in impairment of the nervous system's control of voluntary movement. The most common acquired motor neuron disease, amyotrophic lateral sclerosis (ALS), is a combined upper and lower motor neuron disorder. The features of lower motor neuron involvement are muscle wasting, fasciculations, and flaccid weakness, with normal or depressed tendon reflexes. Upper motor neuron dysfunction may cause increased muscle tone, brisk reflexes, clonus, weakness in a pyramidal distribution, and extensor plantar responses. Recent advances in the molecular genetics of hereditary motor neuron diseases have improved their classification and enhanced the careful diagnosis that is essential for genetic counseling, guidance, treatment, and advising patients about prognosis.

neuropathy (Chapter 384), may manifest with early involvement of the vagus nerve, followed by late development of orthostatic hypotension. Vitamin B_{12} deficiency may occasionally be associated with orthostatic hypotension. Replacement of vitamin deficiencies is important. Alcoholic neuropathy is usually permanent and will progress if drinking continues.

Toxins that may produce peripheral autonomic neuropathy include chemotherapeutic agents, such as vinca alkaloids, platinum derivatives, taxanes, thalidomide, lenalidomide, and bortezomib. Industrial and environmental toxins potentially causing autonomic neuropathy include organic solvents, arsenic, mercury, acrylamide, and thallium (Chapter 20). Organophosphate poisoning (Chapter 96) produces life-threatening cholinergic muscarinic hyperactivity with bradycardia and increased lacrimal, salivary, and bronchial secretions, owing to their inhibition of acetylcholinesterase. Botulinum toxin (Chapter 271) prevents the release of acetylcholine, thereby producing neuromuscular weakness, dilated and unreactive pupils, dry mouth, anhidrosis, constipation, and urinary retention. In contrast, tetanus toxin (Chapter 271) prevents release of γ-aminobutyric acid and glycine in the brain stem and spinal cord, thereby leading to sympathetic hyperactivity that results in tachycardia, hypertension, fever, and profuse sweating.

Some infectious neuropathies may also affect autonomic function. Human immunodeficiency virus (HIV) infections (Chapter 359) may be associated with orthostatic hypotension, tachycardia, cardiac conduction defects, diarrhea, and genitourinary dysfunction. Chagas disease (Chapter 318) affects enteric ganglia, thereby producing megaesophagus and megacolon, as well as causing a cardiomyopathy. Leprosy (Chapter 301) may be associated with focal anhidrosis in areas of hypopigmented and hypoesthesic skin. Autonomic dysfunction has also been observed in some survivors of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection (Chapter 336).[26]

FOCAL CENTRAL NERVOUS SYSTEM DISORDERS

Autonomic dysfunction may be a prominent feature of focal lesions of the brain or spinal cord. Strokes involving the insula (Chapter 376) can be complicated with cardiac arrhythmia, myocardial injury, or, in rare cases, contralateral hyperhidrosis. Temporal lobe seizures (Chapter 372) may manifest with ictal tachycardia or bradycardia (including asystole), ipsilateral piloerection or hypersalivation, episodic abdominal pain and vomiting, and ictal apnea. Paroxysmal hypothermia with hyperhidrosis is a rare hypothalamic disorder characterized by episodic hypothermia associated with excessive sweating, flushing or pallor, bradycardia, weakness, ataxia, and confusion. It may rarely associate with agenesis of the corpus callosum (Shapiro syndrome), but in most cases the cause is unknown. Wernicke encephalopathy (Chapter 384) may be associated with hypothermia. Strokes or neoplasms involving the medulla may manifest with orthostatic hypotension, paroxysmal hypertension, cardiac arrhythmias, vomiting, and respiratory dysfunction, in several combinations.

Disorders of the spinal cord, such as multiple sclerosis (Chapter 380), neuromyelitis optica (Chapter 392), syringomyelia (Chapter 385), and spinal cord injury (Chapter 368), may affect autonomic function. The manifestations and severity of autonomic dysfunction depend on the spinal segment involved, extent of the lesion, and time since the acute injury. Neurogenic bladder, bowel, and sexual dysfunction are a frequent feature. Acute spinal cord injury results in severe hypotension and areflexic bladder, ileus, and impaired response to thermal stimuli. Autonomic dysreflexia, which occurs in patients with spinal cord lesions above the T5 spinal level, consists of reflex sympathoexcitation characterized by severe hypertension, headache, flushing, piloerection, sweating about the level of the lesion, and bradycardia. These episodes can be triggered by bladder distension, fecal impaction, or nociceptive stimuli below the lesion and may result in hypertensive encephalopathy, cerebral or retinal hemorrhage, and cardiac arrhythmias.

REGIONAL SYMPATHETIC DYSFUNCTION

Regional sympathetic dysfunction can be a manifestation of complex regional pain syndrome. This condition, which is often a result of injury, is characterized by pain, hyperalgesia (an exaggerated response to normally painful stimuli), and allodynia (pain in response to stimuli that normally are not painful, such as light touch). These painful symptoms are accompanied by varying combinations of motor, sensory, autonomic, and trophic features. Complex regional pain syndrome can be subdivided into two clinical subtypes: type I, the more common, in which the intensity, duration, and extension of pain are out of proportion to an originally minor or inapparent injury; and type 2, which develops after major nerve damage. The warm subtype of autonomic features is characterized by a warm, red, edematous, and sweaty extremity, whereas the cold subtype manifests as a cold, blue extremity. Most cases are in the upper limbs, and about 80% of cases are in females.[27] The underlying pathobiology is unclear. The sudomotor findings can range from regional hyperhidrosis to anhidrosis. Local dystrophic changes include dry atrophic skin, sparse or coarse hair, brittle nails, and osteopenia.

Early in the syndrome, mobilization of the affected limb may be important, but the evidence base in support of any intervention is limited.[28] Analgesic medications and regional anesthesia may help facilitate physical therapy, which can be helpful.[A11] Improvement has been reported in small studies with interventions such as bisphosphonates (e.g., alendronate), ketamine infusions, corticosteroids (e.g., prednisone or methylprednisolone), epidural clonidine, intrathecal baclofen, and epidural spinal cord stimulation under expert supervision. However, the level of evidence for these interventions is low, and none of these treatments are well established. Most patients improve within 12 months, but a significant proportion of patients have persisting symptoms, ongoing disability, and impaired quality of life.

387 AMYOTROPHIC LATERAL SCLEROSIS AND OTHER MOTOR NEURON DISEASES

PAMELA J. SHAW AND MERIT E. CUDKOWICZ

DEFINITION

The motor neuron diseases (Table 387-1) are a heterogeneous group of disorders in which selective loss of function of upper motor neurons, lower motor neurons, or both results in impairment of the nervous system's control of voluntary movement. The most common acquired motor neuron disease, amyotrophic lateral sclerosis (ALS), is a combined upper and lower motor neuron disorder. The features of lower motor neuron involvement are muscle wasting, fasciculations, and flaccid weakness, with normal or depressed tendon reflexes. Upper motor neuron dysfunction may cause increased muscle tone, brisk reflexes, clonus, weakness in a pyramidal distribution, and extensor plantar responses. Recent advances in the molecular genetics of hereditary motor neuron diseases have improved their classification and enhanced the careful diagnosis that is essential for genetic counseling, guidance, treatment, and advising patients about prognosis.

ABSTRACT

The neurodegenerative motor neuron disorders affect the upper and/or lower motor neurons, thereby resulting in symptoms of limb and/or bulbar weakness. Accurate diagnosis of these conditions is essential to guide treatment options and to allow informed communication of the prognosis and genetic advice. In amyotrophic lateral sclerosis (ALS), cell death of upper and lower motor neurons results in progressive failure of the neuromuscular system affecting limb, bulbar, and respiratory muscles. Average life expectancy is only 2 to 3 years from the onset of symptoms, with death usually resulting from respiratory failure. Characteristic clinical features are of combined upper and lower motor neuron signs in the bulbar, upper, and lower limb regions. Recent progress has been made in the genetic subclassification of ALS and in establishing the value of symptomatic measures such as noninvasive ventilation. Neuroprotective agents such as riluzole, edaravone, and the combination of sodium phenylbutyrate plus taurursodiol have only modest effects on survival and function, but emerging trials of genetic therapy hold promise. Spinal muscular atrophy (SMA) is an autosomal recessive lower motor neuron disorder with four grades of clinical severity (SMA types I to IV), most commonly caused by a deletion in the *SMN1* gene and resulting deficiency of the survival motor neuron protein. Recent gene therapy and antisense oligonucleotide trials to increase SMN protein levels have shown evidence of efficacy and have improved the prognosis. Kennedy disease is an X-linked lower motor neuron disorder caused by a CAG expansion in exon 1 of the androgen-receptor gene. Features of androgen insensitivity are likely to be present as well as mild distal sensory abnormalities. The disease course is relatively indolent compared with ALS.

TABLE 387-1 CLASSIFICATION OF MOTOR NEURON DISORDERS

COMBINED UPPER AND LOWER MOTOR NEURON DISORDERS
Amyotrophic lateral sclerosis (ALS)
Familial adult onset
Familial juvenile onset
Sporadic
ALS-plus syndromes
ALS with frontotemporal dementia
Western Pacific ALS–parkinsonism-dementia complex
UPPER MOTOR NEURON DISORDERS
Primary lateral sclerosis
Hereditary spastic paraplegias
Neurolathyrism
Konzo
LOWER MOTOR NEURON DISORDERS
Hereditary
Spinal muscular atrophies (SMAs)
Proximal autosomal recessive SMA (associated with *SMN* mutations) types I to IV
Other forms of SMA not associated with *SMN* mutations
Distal SMAs/hereditary motor neuronopathies
Kennedy disease (X-linked spinobulbar neuronopathy)
Hexosaminidase deficiency (GM2 gangliosidosis)
Acquired
Monomelic focal and segmental SMAs
Multifocal motor neuropathies
Acute motor axonal neuropathy (AMAN)
Post-polio syndrome
Post-irradiation syndrome
Infective disorders
Acute poliomyelitis
West Nile fever
Other viral infections (e.g., enterovirus 71 and rabies virus)
Human immunodeficiency virus–associated motor neuron disorder
Lyme disease
Creutzfeldt-Jakob disease (amyotrophic form)
DISORDERS OF THE BULBAR MOTOR SYSTEM
Kennedy disease (X-linked bulbospinal neuronopathy)
Brown-Vialetto-Van Laere syndrome
Fazio-Londe disease
TOXIC DISORDERS OF THE MOTOR NEURON
Neurolathyrism
Konzo
Heavy metal toxicity (lead, mercury)
Western Pacific ALS–parkinsonism-dementia complex
Post-irradiation motor neuron injury
DISORDERS OF MOTOR NEURON OVERACTIVITY
Neuromyotonia
Stiff person syndrome
MISCELLANEOUS MOTOR NEURON DISORDERS
Endocrinopathies (e.g., hyperthyroidism, hyperparathyroidism, hypoglycemia)
Copper deficiency syndrome
Benign cramp-fasciculation syndrome

AMYOTROPHIC LATERAL SCLEROSIS

EPIDEMIOLOGY

ALS is a neurodegenerative disorder that causes progressive injury and cell death of lower motor neurons in the brain stem and spinal cord, as well as upper motor neurons in the motor cortex.[1] ALS has an incidence of about 2 per 100,000 and a prevalence of 6 to 8 per 100,000. The global incidence is fairly uniform, with the exception of a few high-incidence foci such as the Western Pacific island of Guam. The disease affects predominantly middle-aged and elderly individuals, with a mean age at onset of 55 to 60 years, although younger individuals can also be affected. Increasing age, male sex (male/female ratio ≈ 1.6 : 1), and genetic susceptibility are the only proven risk factors, although strenuous physical exercise, head trauma, and lead exposure may also be potential environmental risk factors[2,3] Approximately 90% of cases of ALS occur sporadically, but 5 to 10% are familial, usually with an autosomal dominant mode of inheritance.

PATHOBIOLOGY

The process of neuronal degeneration in ALS is complex, and more than 40 ALS susceptibility genes have been identified. GGGGCC hexanucleotide intronic expansions in the chromosome 9 *C9ORF72* gene are the most common genetic cause of ALS identified to date, accounting for up to 40 to 50% of familial ALS cases and 7 to 10% of sporadic ALS.[4] Accumulating evidence suggests that defective RNA processing likely plays a key role in the pathogenesis of *C9ORF72* ALS as well as other genetic subtypes. The pathobiology of C9-ALS is not yet completely understood, but the sequestration of RNA binding proteins by RNA foci and altered nucleocytoplasmic transport that allows the expansion RNA to translate into dipeptide repeat proteins in the cytoplasm are clearly of key importance.

The subtype of disease caused by *SOD1* mutations accounts for 20% of familial ALS cases and 2% of ALS cases overall. Mutant *SOD1* appears to transmit templated propagation in a prion-like (Chapter 378)[5] fashion, with these aggregates then triggering a complex interplay of multiple pathogenic processes, including oxidative stress, protein aggregation, mitochondrial dysfunction, excitotoxicity, and impaired axonal transport. Non-neuronal cells in the vicinity of motor neurons may contribute importantly to neuronal injury. Genetically engineered mouse models of *SOD1*-related ALS have shown that normal astrocytes can protect motor neurons expressing mutant *SOD1* and that removing the expression of mutant *SOD1* from microglia or astrocytes slows the progression of disease in these murine models. Astrocytes expressing mutant *SOD1* exert toxic effects on neighboring motor neurons through as yet undefined mechanisms.

Familial motor neuron disease has been linked to mutations involving alsin, senataxin, angiogenin, *VAPB*, dynactin, *TARDBP, TBK1, FUS/TLS*, and multiple other genes.[6] Intermediate-length polyQ expansions (27-33Q) in ataxin 2 are found as a risk factor for ALS in approximately 5% of patients. Associations have been reported with alterations in at least eight other genes in cases that appear sporadic. Large combined genome-wide association studies suggest that rare genetic variants underpin 15 to 20% of cases of sporadic ALS.

Pathology

At autopsy, the gross pathologic features of ALS consist of atrophy of the cerebral precentral gyrus, as well as sclerosis and pallor of the corticospinal tracts of the spinal cord. Thinning of the hypoglossal nerves and ventral spinal roots may be observed, and muscle atrophy is obvious. Microscopically, ALS patients will typically have lost at least 50% of their spinal motor neurons and have diffuse astrocytic gliosis in the spinal gray matter. By comparison, motor neurons in Onuf nucleus in the sacral spinal cord (which innervate the pelvic floor muscles) and the motor nuclei of cranial nerves III, IV, and VI (which control eye movements) are relatively preserved. A cardinal feature in residual motor neurons is the presence of ubiquitinated proteinaceous inclusions, which may be compact or skeinlike. TDP-43 has been recognized as a major protein constituent of these aggregates. In the motor cortex, there is variable loss of upper motor neurons and astrocytic gliosis. In the descending corticospinal tracts, axonal loss, myelin pallor, and gliosis are seen. The atrophied skeletal muscle shows clusters of angular atrophic fibers and fiber-type grouping that results from serial denervation and reinnervation. The selectivity of the disease process for the motor system is now recognized to be relative, and involvement of extra-motor parts of the central nervous system can be found, especially in the sensory and spinocerebellar pathways, substantia nigra neurons, and dentate granule cells in the hippocampus. In the ALS variant caused by *C9ORF72* expansions, the characteristic extra-motor system pathology demonstrates cerebellar and hippocampal inclusions that are P62+ and TDP-43-negative by immunostaining. Some of these inclusions comprise dipeptide proteins generated by aberrant translation of the hexanucleotide repeats.

CLINICAL MANIFESTATIONS

ALS is characterized by a combination of upper and lower motor neuron degeneration. Lower motor neuron degeneration causes weakness, atrophy, and fasciculation of the limb and bulbar musculature. Features of upper motor neuron dysfunction include the incongruous presence of active or brisk tendon reflexes in a wasted limb, increased muscle tone, and sometimes the presence of the Babinski sign. Upper motor neuron bulbar disease causes pseudobulbar palsy, with emotional lability, a brisk jaw jerk, slowing of repetitive tongue movements, and strained effortful speech. Fatigue and weight loss are also common symptoms. At end-stage disease, most patients will have features of upper and lower motor neuron dysfunction affecting all four limbs and the bulbar musculature.

In approximately 75% of patients, the disease starts distally, focally, and asymmetrically in an upper or lower limb (Video 387-1), followed by progressive spread of pathology in an anatomically logical progression to contiguous groups of motor neurons. Affected individuals may notice weakness, wasting or clumsiness of one hand, or unilateral footdrop. Muscle cramps may precede other clinical features, and fasciculations are most noticeable in the large proximal limb muscles. In the upper limbs, the thenar and intrinsic hand muscles tend to be severely affected, whereas the triceps and finger flexors are relatively spared until late in the disease. In the lower limbs, the pattern of weakness is often in a pyramidal distribution (flexors weaker than extensors), with early weakness of hip flexion and ankle dorsiflexion and severe involvement of the distal muscles.

Bulbar symptoms, which are the initial feature in approximately 25% of patients, are especially common in elderly women with ALS (Video 387-2). The first problem is usually slurring of speech, initially apparent only when the individual is tired. Patients often have a mixed spastic/flaccid dysarthria in which speech develops a tight strangled quality because of the upper motor neuron component, with a superimposed nasal quality as a result of the flaccid lower motor neuron weakness of the palate and nasopharynx. In patients with bulbar disease, examination often reveals weakness of the facial muscles; a spastic, weak, wasted, and fasciculating tongue; and a brisk jaw jerk. Dysphagia, initially more pronounced for liquids than for solids, usually follows the dysarthria within a few weeks or months (Video 387-3). Complications include weight loss and prolonged and arduous meal times with frequent episodes of coughing, drooling of saliva, and aspiration pneumonia.

Respiratory muscle weakness is rarely the initial feature of ALS. More commonly, respiratory muscle weakness develops insidiously and causes dyspnea and orthopnea. Diaphragmatic weakness may be apparent from the paradoxical movement of the abdominal wall during inspiration and a marked decline in forced vital capacity in the supine position. Symptoms of nocturnal carbon dioxide retention may develop, including interrupted sleep, morning headaches, anorexia, and daytime somnolence.

Neck muscle weakness, which is common later in the course of the disease, causes difficulty holding the head upright (dropped head syndrome). Eye movements tend to be spared even in advanced disease, thereby permitting limited communication by movements of the eyes. Similarly, the strength of the pelvic floor muscles is relatively preserved, so patients with ALS usually remain continent throughout the course of the disease.

Overt features of frontotemporal dementia (Chapter 371), with progressive deterioration in personality and behavior,[7] will develop in approximately 5% of patients with ALS. Cognitive dysfunction may precede, follow, or coincide with the features of motor dysfunction. Up to 50% of ALS patients without overt dementia may show more subtle features of frontal lobe dysfunction. The C9ORF72-ALS variant causes both ALS and/or frontotemporal dementia (Chapter 371), and patients with this subtype of ALS are more likely to have cognitive disturbances as well as a family history of dementia or psychosis.

About 5 to 10% of ALS patients have the progressive muscular atrophy variant, with clinical features reflecting only degeneration of lower motor neuron groups in the spinal cord. In primary lateral sclerosis, patients have pure upper motor neuron degeneration. Although severe spastic spinobulbar paresis ultimately develops in these patients, the duration of survival is commonly 10 to 15 years after the onset of symptoms. The progressive bulbar palsy variant usually progresses to involve the limbs, although limb signs may not be present initially.

Several ALS variants follow a more segmental pattern than is typical in ALS. Up to 10% of patients with ALS have flail arm syndrome, which is more common in men and is associated with a longer median survival than seen in those with typical ALS. A similar focal manifestation in the lower limbs, flail leg syndrome, is another recognized segmental variant.

DIAGNOSIS

The diagnosis of ALS is essentially clinical, and there currently is no specific diagnostic test. Nevertheless, biomarkers of motor neuron injury, including elevated levels of neurofilament light and phosphorylated neurofilament heavy in cerebrospinal fluid (CSF), and plasma have promise for the future.[8]

Diagnosis requires evidence of lower motor neuron degeneration by clinical, electrophysiologic (Chapter 366), or neuropathologic examination; upper motor neuron degeneration by clinical examination; and progressive spread of symptoms or signs within a region or to other regions, as determined by the history or examination. The diagnosis also requires the absence of other disease processes as determined by electrophysiologic testing, neuroimaging, and blood tests. Generally accepted criteria (Table 387-2) classify patients as having definite, probable, or possible ALS. However, a number of other conditions may mimic ALS (Table 387-3), and about 8% of patients in whom ALS is initially diagnosed have other lower motor neuron syndromes, such as multifocal motor neuropathy with conduction block, Kennedy disease, or mixed spinal cord and nerve root compression (Chapter 369). Conversely, 10 to 15% of patients in whom ALS is ultimately diagnosed may first undergo inappropriate surgery for presumed spinal cord or root compression abnormalities.

TABLE 387-2 AWAJI-SHIMA CONSENSUS CRITERIA FOR DIAGNOSING AMYOTROPHIC LATERAL SCLEROSIS

The diagnosis of ALS requires:
1. Evidence of LMN loss (reduced interference pattern on full contraction and increased firing rate)
2. Evidence of reinnervation (motor units of large amplitude and longer duration)
3. Fibrillation and sharp waves or fasciculation potentials (fibrillation and sharp waves are required in weak limb muscles)

Number of muscles affected by region:
- Cervical and lumbo-sacral region: a minimum of 2 muscles innervated by different roots and nerves
- Bulbar and thoracic region: a minimum of 1 muscle

Diagnostic classification: Awaji-Shima Consensus Recommendations and the Revised El Escorial Criteria
- Clinically definite ALS:
  - Clinical or electrophysiologic evidence of the presence of LMN as well as UMN signs in the bulbar region and at least 2 spinal regions or the presence of LMN and UMN signs in 3 spinal regions
- Clinically probable ALS:
  - Clinical or electrophysiologic evidence of LMN and UMN signs in at least 2 regions, with some UMN signs necessarily rostral to (above) the LMN signs
- Clinically possible ALS:
  - Clinical or electrophysiologic signs of UMN and LMN dysfunction are found in only 1 region, or UMN signs are found alone in ≥2 regions, or LMN signs are found rostral to UMN signs

ALS = amyotrophic lateral sclerosis; LMN = lower motor neuron; UMN = upper motor neuron.
UMN signs: clonus, Babinski sign, brisk tendon reflexes, absent abdominal reflexes, hypertonia, loss of dexterity.
LMN signs: atrophy, weakness. If only fasciculation, search with electromyography (EMG) for active denervation. Regions reflect segmental motor neuron pools: bulbar, cervical, thoracic, and lumbosacral.
Adapted from Costa J, Swash M, de Carvalho M. Awaji criteria for the diagnosis of amyotrophic lateral sclerosis: a systematic review. *Arch Neurol*. 2012;69:1410-1416.

Blood tests that may be helpful in distinguishing ALS from mimic syndromes (see Table 387-3) include a complete blood count and serum calcium level, thyroid function tests, parathyroid hormone, serum protein electrophoresis, Venereal Disease Research Laboratory test, creatine kinase level, inflammatory markers (erythrocyte sedimentation rate and C-reactive protein), and levels of anti-GM1 ganglioside and anti–myelin-associated glycoprotein (MAG) antibodies. Further testing, which is guided by the patient's clinical findings, might include acetylcholine receptor antibody; mutation screening in patients with familial disease, suspected Kennedy disease, or spinal muscular atrophy (SMA); heavy metal screening; urinary porphyrins; serum hexosaminidase A and B levels; *Borrelia* titers; and testing for human immunodeficiency virus.

Typical features of ALS on electromyography (EMG) include evidence of active denervation (i.e., positive sharp waves, fibrillation, and fasciculation potentials) and chronic denervation, as evidenced by large motor unit potentials that cannot be explained by a single nerve, root, or plexus lesion. Neuroimaging of the brain and spinal cord is usually needed to exclude structural pathology.

Baseline respiratory function tests should be performed on all patients. Muscle biopsy is indicated only in atypical cases when diagnostic uncertainty persists.

In the current era of emerging trials of genetic therapy, a case can be made for offering genetic panel screening to patients with both sporadic and familial ALS.[9]

TREATMENT

ALS is best managed in specialized centers that offer multidisciplinary care. Teams typically include a neurologist, nurse specialist, occupational therapist, physical therapist, speech and language therapist, and dietitian. During the course of the disease, patients frequently require referral for placement of a gastrostomy tube[10] and for provision of respiratory support.

TABLE 387-3 DISORDERS THAT CAN MIMIC AMYOTROPHIC LATERAL SCLEROSIS/MOTOR NEURON DISEASE

FORM OF MOTOR NEURON DISEASE	MIMIC SYNDROMES	CLINICAL CLUES
Progressive muscular atrophy (PMA)/LMN-predominant phenotype	Multifocal motor neuropathy	Weakness out of proportion to wasting. Neurophysiology identifies conduction block. Anti-GM1 antibodies may be raised.
	Kennedy disease	Gynecomastia, distal sensory features, perioral fasciculation, indolent progression.
	SMA	SMA can be adult onset. Pure LMN syndrome. Slower progression than PMA. Probably no family history.
	Chronic idiopathic demyelinating polyneuropathy	Electrophysiology identifies peripheral nerve demyelination. CSF protein likely to be raised.
	Benign cramp-fasciculation syndrome	Predominantly middle-aged men. Largely calf involvement. Failure to progress. No active denervation on EMG.
	Post-polio syndrome	Pure LMN syndrome. Past history of an illness compatible with poliomyelitis. Indolent progression.
	Lead poisoning	Extramotor clinical features (e.g., constipation, nail and buccal signs).
	Acute motor axonal neuropathy (AMAN—a Guillain-Barré syndrome variant)	Acute onset, with progression ceasing after a few weeks. Nerve conduction studies show features of motor axonopathy.
	Hereditary motor neuropathies	Pure LMN syndrome. Family history, clinical signs indicating chronicity, slower rate of progression.
	Porphyria	Extramotor clinical features, family history, episodic exacerbations.
	Compressive focal motor neuropathies	Pure motor disorders can result from compression of the deep palmar branch of the ulnar nerve and posterior interosseous branch of the radial nerve. Failure to extend beyond territory of one nerve. Electrophysiology with or without imaging helpful.
ALS	Multilevel spinal cord and root compression by discs, osteophytes, or tumor	Sensory symptoms and pain are common. UMN signs often caudal to LMN signs.
	Thyrotoxicosis	Systemic symptoms and signs.
	Combined peripheral neuropathy and cervical myelopathy	MRI of the spine and electrophysiology will differentiate.
	Inclusion body myositis	Rarer than ALS. Characteristic pattern of weakness with early involvement of the long finger flexors and quadriceps.
	Paraneoplastic syndromes, especially lymphoma	History of malignancy or systemic features.
	Sjögren syndrome	Non–motor-related symptoms.
	Radiation myelopathy	History of radiotherapy.
	Structural lesions of the bulbar region (e.g., tumor of the tongue base)	Pain, failure of features to extend outside the bulbar territory.
Primary lateral sclerosis	Hereditary spastic paraplegia	Family history. Symptoms rarely extend beyond the lower limb territory. Prominent bladder dysfunction.
	Multiple sclerosis	Non–motor-related symptoms and signs (e.g., eye, bladder, cerebellar, and sensory involvement).
	Spinal cord compression by disc or tumor	Pain and sensory involvement usually present.

ALS = amyotrophic lateral sclerosis; CSF = cerebrospinal fluid; EMG = electromyography; LMN = lower motor neuron; MRI = magnetic resonance imaging; SMA = spinal muscular atrophy; UMN = upper motor neuron.

Riluzole, a sodium channel blocker whose primary mechanism of action is to reduce excitotoxicity through inhibition of presynaptic glutamate release, prolongs survival by approximately 3 months when given at 50 mg twice daily.[11] It may cause fatigue, nausea, and dizziness, but these effects are frequently transient. Liver function tests should be performed at baseline and monthly for the first 3 months of therapy. Edaravone (an intravenous injection, initially daily for 14 days, then 14 days off, and then given as cycles thereafter) is an antioxidant that is approved in Japan, South Korea, and the United States; it can slow the progression of disease by approximately one third in patients who have early ALS and preserved vital capacity.[A1] Sodium phenylbutyrate (3 g) and taurursodiol (1 g) administered orally (daily for 3 weeks and then twice daily) to reduce neuronal death by mitigating endoplasmic reticulum stress and mitochondrial dysfunction can slow functional decline and prolong survival by a median of 6.5 months compared with placebo.[A2,A3]

For patients with mutations in *SOD1*, antisense nucleotide technology and gene therapy are potential options.[12] Intrathecal tofersen, which is an antisense oligonucleotide that catalyses the degradation of SOD1 messenger RNA and reduces synthesis of the SOD1 protein, substantially decreases CSF SOD1 protein levels and neurofilament light levels and results in clinical benefit at 12 months.[13] Intrathecal infusion of an adeno-associated virus encoding a microRNA targeting SOD1 also has shown promise.[14]

Other phase III trials of potential neuroprotective therapies have so far proved negative. Experimental approaches include troponin activators to improve muscle contraction.

Good clinical care must focus on symptoms and preservation of independence and quality of life. Mexiletine (300 mg/day) can significantly reduce the frequency and severity of muscle cramps.[A4] In patients with progressive bulbar problems, optimal positioning, attention to food and fluid consistency, and protective swallowing techniques are helpful. Nuedexta (a combination of 20 mg dextromethorphan and 10 mg quinidine once daily) can improve symptoms of pseudobulbar affect (inappropriate tearfulness and laughter) and is also currently under study for symptoms of swallowing and speech dysfunction.[A5] If weight loss continues, high-calorie nutritional supplements are added between meals. In ALS patients with dysphagia due to upper motor neuron impairment of the upper esophageal sphincter, local injection of botulinum toxin type A can significantly improve the dysphagia and may represent an alternative to percutaneous endoscopic gastrostomy. Placement of a gastrostomy tube via endoscopy or under radiologic guidance is recommended in patients in whom dehydration, weight loss of 10 to 15%, frequent distressing choking episodes, prolonged and tiring mealtimes, or aspiration pneumonia develop. Tube placement is higher risk in patients with respiratory insufficiency. Tubes should ideally be placed before the patient's forced vital capacity falls below 50% of predicted. Some evidence suggests that radiologically guided gastrostomy insertion may be safer in frail patients in the late stages of ALS.

Respiratory muscle weakness, which can develop insidiously during the course of ALS, causes breathlessness, orthopnea, daytime somnolence, morning headaches, and interrupted sleep. Aerobic exercise,[A6] especially if combined with strength training,[A7] can significantly slow the decline of respiratory function. Management must emphasize detection and prevention of aspiration pneumonia, assistance in clearing of secretions by agents to reduce saliva production (e.g., anticholinergic drugs such as transdermal hyoscine, amitriptyline, glycopyrrolate, or intrasalivary botulinum toxin injections), providing a suction machine, use of a mucolytic agent such as carbocisteine (in a dose of up to 750 mg three times daily), adoption of a semi-upright position for sleep, and aggressive antibiotic therapy for chest infection (Chapters 84 and 85). A small dose of sublingual lorazepam (0.5 to 1 mg) may be useful if dyspnea is accompanied by extreme anxiety; opiate therapy (e.g., morphine, diamorphine, fentanyl [Chapter 26, Table 26-4]) may be given orally, transdermally, or by subcutaneous infusion to relieve respiratory distress during the later stages of the disease.

As respiratory function worsens, noninvasive ventilation[15] can alleviate symptoms of chronic hypoventilation, significantly improve quality of life, and prolong survival,[A8] especially in patients with orthopnea, daytime hypercapnia,

and nocturnal oxygen desaturation. Full 24-hour ventilation via a tracheostomy is an option that is chosen uncommonly by fully informed patients. Diaphragm muscle pacing appears to worsen the course of the disease in ALS.[A9] Ongoing clinical research is evaluating the value of cough assist devices, as well as the optimal way to manage respiratory symptoms at the end of life. An experimental fully implanted brain-computer interface has allowed communication at the equivalent of two letters per minute in a locked-in patient with ALS.

Multidisciplinary teams can improve symptoms and perhaps survival.[16] Palliative care teams and hospices can contribute substantially to the care of ALS patients in the later stages of the disease. In the absence of ventilatory support, ALS patients will almost always die in their sleep from hypercapnic coma. In the terminal phases (Chapter 3), the aim of treatment is to ensure comfort by prescribing opiates and anxiolytic medications as required to alleviate discomfort or distress.

PROGNOSIS

Clinical features associated with a worse prognosis include older age at onset of symptoms, compromise of respiratory function, bulbar symptoms, and more rapid presentation to medical attention. The mean duration from the onset of symptoms to death in patients with sporadic ALS ranges from 27 to 43 months. The average 5-year survival rate is 25%, and approximately 5% of patients will survive for more than 10 years. The usual cause of death is respiratory failure, which may be accompanied by bronchopneumonia.

SPINAL MUSCULAR ATROPHIES

DEFINITION

The term *spinal muscular atrophy* encompasses a group of pure lower motor neuron disorders that cause progressive symmetrical muscle weakness and wasting.[17] Because the bulbar musculature may be affected, an alternative term, *hereditary motor neuronopathy*, has been proposed. The time of onset is variable and ranges from in utero to adult life.

EPIDEMIOLOGY AND PATHOBIOLOGY

The most common type of SMA is caused by mutations in the survival motor neuron (*SMN*) gene and is inherited as an autosomal recessive disorder. The estimated carrier frequency of an *SMN* mutation is 1 in 50. Type 1 SMA (Werdnig-Hoffmann disease) has an incidence of 1 in 8000 births. SMA is divided into subtypes I to IV according to age at onset and severity of the phenotype.

The human *SMN* gene on chromosome 5q13 exists in two forms, with five base-pair differences between *SMN1* and its centromeric homologue *SMN2*. A change in exon 7 of *SMN2* leads to skipping of exon 7, and as a result, 80% of the protein encoded by *SMN2* is truncated and nonfunctional rather than full length. The majority of patients with SMA have homozygous absence of *SMN1* exon 7, but *SMN1* may be replaced by a copy of *SMN2* during DNA replication by a process known as gene conversion. An individual may have one to four copies of *SMN2*, with a proportional increase in the amount of full-length SMN protein. A molecular basis for the wide variation in the phenotypic severity of SMA, which can range from in utero onset (SMA type I) to adult onset (SMA type IV), is the number of copies of *SMN2* and the SMN protein levels, although other disease-modifying factors have also been implicated.

The SMN protein oligomerizes and associates with other proteins to form the SMN complex, which in turn has an important role in the assembly of spliceosomal small nuclear ribonucleoproteins that have a function in pre-mRNA splicing in the nucleus. These cellular processes are ubiquitous, so either the clinical features of SMA may be caused by a particular susceptibility of lower motor neurons to defects in RNA processing or SMN may have additional functions that are specific to the motor neuron, including axonal transport of mRNA molecules essential for the health of the distal axon. Recent work has highlighted the role of dysregulation of ubiquitin homeostasis and β-catenin signaling, as well as genes involved in motor neuron synaptogenesis in the pathophysiology of SMA.

At autopsy, patients with SMA have atrophic spinal cords with loss of α-motor neurons and evidence of motor neuron degeneration and gliosis. The ventral roots are atrophic, and muscle atrophy is apparent, with microscopic evidence of denervation and reinnervation.

CLINICAL MANIFESTATIONS

Type I SMA (Werdnig-Hoffman disease) is characterized by severe generalized muscle weakness and hypotonia at birth or by the age of 6 months; affected children never sit or walk. Type II is an intermediate form with an onset of muscle weakness before the age of 18 months; patients can sit but are never able to walk unaided. Type III SMA (Wohlfart-Kugelberg-Welander disease) appears after 18 months of age; patients acquire the ability to stand and walk but often become wheelchair dependent in adolescence or adult life, although life expectancy is normal. Patients with type IV SMA have onset of muscle weakness in adult life.

DIAGNOSIS

The diagnosis of SMA caused by changes in *SMN* can be made by genetic testing in a patient with appropriate clinical signs and symptoms; 95% of affected individuals have *SMN* deletions. Prenatal diagnosis is available. Electrophysiology and muscle biopsy reveal evidence of denervation.

Other disorders can present in infancy or childhood as hypotonia, and a pattern of weakness similar to *SMN*-related SMA can be distinguished by associated clinical features such as early respiratory distress or vocal cord paralysis, or an atypical distribution of motor features such as upper limb–or lower limb–predominant or scapulo-peroneal involvement. The etiologic relationship of these disorders to classic SMA can be clarified by testing for *SMN* mutations.

It is important to distinguish SMA type I from infantile botulism, which can have a similar initial clinical picture. EMG with high-frequency repetitive nerve stimulation shows a decrement in botulism, and testing for the presence of botulinum toxin can confirm the diagnosis (Chapter 271). SMA II and SMA III can be distinguished from chronic inflammatory demyelinating polyneuropathy (Chapter 388) by the presence of normal CSF protein and normal nerve conduction studies in SMA. Patients with SMA type III can have clinical features that are similar to those of the hereditary motor and sensory neuropathies, but it can be distinguished by neurophysiologic assessment and genetic testing.

TREATMENT AND PROGNOSIS

Approaches to upregulate expression of the SMN protein include the intravenous infusion of an adenoviral vector that contains the DNA that codes for SMN. Nusinersen (an antisense oligonucleotide drug that modifies the pre–messenger RNA splicing of the *SMN2* gene) promotes increased production of full-length SMN protein and improves motor function in infants and children with spinal muscular atrophy[A10,A11] for at least 3 years.[18] Risdiplam (an oral small molecule with actions similar to nusinersen) also can increase blood levels of SMN protein and potentially improve function.[A12,19,20] Similar results have also been reported for onasemnogene abeparvovec.[21,22]

Children with SMA may benefit from passive and active physical therapy, lightweight braces, surgical correction of scoliosis, and respiratory support measures. Untreated patients with type I SMA usually die by the age of 2 years, untreated patients with type II SMA typically survive into adolescence, and patients with type III and type IV have a normal life expectancy. New treatments appear to hold great promise for improving this prognosis.

SPINOBULBAR MUSCULAR ATROPHY/ KENNEDY DISEASE

EPIDEMIOLOGY

Kennedy disease, or spinobulbar muscular atrophy, is an X-linked degenerative disorder of the lower motor neurons.[23] Though rare, it is important not to miss the diagnosis because of the genetic implications for the family and a more benign course than occurs with ALS. The diagnosis should be considered in any male patient with a pure lower motor neuron disorder, particularly when the disease course is relatively indolent, gynecomastia is present, or there is evidence of a mild accompanying sensory neuropathy.

PATHOBIOLOGY

Spinobulbar muscular atrophy is a trinucleotide repeat disorder in which a CAG expansion encodes for a polyglutamine tract in the first exon of the androgen receptor gene on chromosome Xq11-12. The androgen receptor, which contains three functional domains, is transported to the nucleus, where it binds to DNA and acts as a transcription factor. Expansion of the polyglutamine tract results in reduced target gene transactivation, and neurodegeneration occurs when the polyglutamine tract reaches a critical length of approximately 40 repeats. The neurodegeneration in patients with spinobulbar muscular atrophy is considered to result from a ligand-dependent toxic gain of function of the mutant androgen receptor protein. Complete loss of its function, as seen in testicular feminization syndrome (Chapter 214), does not lead to motor neuron degeneration. The toxicity

has not been fully characterized, but protein aggregation, impairment of protein degradation pathways, disruption of gene transcription, impairment of axonal transport, and altered neurotrophic factor signaling may all contribute.

Pathologic examination reveals mild spinal cord atrophy with ventral horn gliosis and loss of α-motor neurons. Misfolding of the polyglutamine (Q)–expanded protein leads to the formation of nuclear inclusions that contain the amino-terminal epitopes of the mutant androgen receptor within motor neurons and certain non-neuronal tissues.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The mean age at onset of spinobulbar muscular atrophy is 30 years, with a range of 15 to 60 years, and the severity of the disease and its age at onset correlate with the size of the repeat expansion. Initial symptoms consist of hand tremors, fasciculations, and muscle cramps, followed by progressive weakness and atrophy of the limb and bulbar muscles. Limb muscle weakness tends to be proximal and predominantly involves the lower limbs. There are no clinical signs of upper motor neuron dysfunction. Weakness of the lower facial and tongue muscles causes dysarthria, and jaw weakness may cause the mouth to hang open. The presence of perioral fasciculations with quivering of the chin is a characteristic feature. Pharyngeal involvement can cause dysphagia, and respiratory muscle weakness causes breathlessness. Mild distal sensory loss is frequently present in the lower limbs. Features of mild androgen insensitivity are frequent: gynecomastia, testicular atrophy, and erectile dysfunction. Heterozygous female carriers of spinobulbar muscular atrophy may show mild clinical manifestations of the disease.

EMG and muscle biopsy, which is often performed because the creatine kinase level tends to be elevated, reveal evidence of chronic denervation. Genetic screening for the CAG repeat expansion in exon 1 of the androgen receptor gene is diagnostic.

TREATMENT AND PROGNOSIS

Because there are no established disease-modifying therapies for spinobulbar muscular atrophy, current therapy consists of supportive care to prevent complications. The course of the disease is slowly progressive in comparison to ALS and is compatible with normal life expectancy, although some patients may die of respiratory failure. Patients may become wheelchair dependent over a period of 2 to 3 decades, but some remain ambulatory until late in life.

PERIPHERAL NEUROPATHIES

A. GORDON SMITH AND MICHAEL E. SHY

APPROACH TO PERIPHERAL NEUROPATHY

The term *peripheral neuropathy* is used to describe a group of disorders that are caused by injury to the peripheral nervous system, which encompasses the final pathways of motor, sensory, and autonomic function.

EPIDEMIOLOGY

As a group, peripheral neuropathies are among the most common neurologic problems encountered in medical practice. The prevalence of peripheral neuropathy increases with age from 2 to 3% in individuals who are 50 to 60 years of age to 13% among individuals who are 70 to 80 years of age and greater than 30% among individuals over age 80 years. The population prevalence of peripheral polyneuropathy in the United States is 2.4% overall but rises to as high as 50% among individuals over 85 years of age. The most common cause of polyneuropathy is diabetes, which accounts for approximately 50% of cases. Most of the remainder have cryptogenic sensory peripheral neuropathy, although over 50% of this population has prediabetes. Other common causes of neuropathy include genetic, inflammatory, metabolic, and toxic etiologies.

PATHOBIOLOGY

Motor neurons extend from their cell body in the ventral horn of the spinal cord through the ventral nerve roots and peripheral nerves to the neuromuscular junctions at the muscle that they innervate. The cell bodies of primary sensory neurons lie outside the spinal cord in the dorsal root ganglia, where they extend peripherally to specialized sensory end organs, including nociceptors (pain receptors), thermoreceptors, and mechanoreceptors. Central projections from dorsal root ganglia enter the spinal cord through the dorsal roots to carry sensory information to the central nervous system (CNS). At each spinal segment, the ventral roots, which carry motor axons, and the dorsal roots, which carry sensory axons, join to form mixed sensorimotor nerves. In the proximal upper and lower extremities, the mixed spinal nerves form the brachial and lumbar plexuses from which arise the major anatomically defined limb nerves. Each mixed nerve is composed of a spectrum of nerve fibers, damage to which causes specific but overlapping symptoms and signs. Large-diameter myelinated fibers are responsible for motor function, proprioception, and touch sensation, whereas small-diameter lightly myelinated and unmyelinated axons are responsible for pain and autonomic function. Preganglionic sympathetic autonomic fibers begin in the intermediolateral column of the spinal cord and synapse in ganglia of the sympathetic trunk. Preganglionic parasympathetic fibers travel long distances from their cell bodies in the brain stem or sacral spinal cord to reach terminal ganglia near the organs that the parasympathetic fibers innervate.

Although positive sensory symptoms occur with injury to both large- and small-diameter fibers, severe painful sensations, particularly burning, usually suggests preferential injury to small-diameter axons. Because motor axons are capable of reinnervating denervated muscle fibers via collateral sprouting, weakness does not develop in axonal neuropathies until about 50% of axons have been injured.

CLINICAL MANIFESTATIONS

The clinical features of a peripheral neuropathy are dependent on the involved regions. Most patients with peripheral neuropathy have a chronic axonal sensory greater than motor peripheral polyneuropathy and present with slowly progressive sensory symptoms.

Sensory and motor symptoms may be divided into negative (loss of function) and positive (abnormal function). Common negative sensory symptoms include a general sense of numbness or loss of sensation, such as feeling as if feet are "walking on pebbles" or "ice cold," difficulty determining whether bath water is hot or cold with the foot, and loss of balance, particularly in the dark when visual compensation is difficult. Positive symptoms include painful dysesthesias, such as feeling as though the feet are "on fire," "on hot coals," or "stuck with pins." If severe, the symptoms may reach the level of the knee, at which point the fingers may become involved. Motor symptoms

If severe, the symptoms may reach the level of the knee, at which point the fingers may become involved. Motor symptoms

ABSTRACT

Peripheral neuropathies are among the most common neurologic disorders encountered in general medical practice. Common causes include inflammatory, inherited, toxic, and metabolic disorders, with diabetes being the most common etiology. Effective treatments are available for many forms, and promising therapeutics are in development for others.

KEYWORDS

polyneuropathy
Guillain-Barré syndrome
diabetic neuropathy
Charcot-Marie-Tooth disease
neurotoxicity

and signs are typically mild and limited to subtle weakness of toe extension and flexion, with atrophy of foot muscles. There may be mild gait instability that does not require the use of assistive devices. Foot ulceration is absent. Gait imbalance owing to a sensory ataxia (instability worse with eyes closed) indicates large fiber involvement or dysfunction of the dorsal columns of the spinal cord. Sensory ataxia involving the upper extremities is manifest by impaired coordination and finger-nose-finger testing that is worse with eyes closed, when there are often writhing, "pseudoathetoid" movements of the fingers with arms outstretched.

Involvement of motor nerves results in muscle weakness and, over time, atrophy. In peripheral polyneuropathies weakness involves distal muscles in the legs more than the arms. Deep and superficial muscles that are innervated by the peroneal nerve, such as the tibialis anterior and peroneus brevis and longus muscles, are usually affected first. As a result, tripping on a carpet or curb and ankle sprains are frequent symptoms. In the hands, symptoms typically involve fine movements, such as using buttons or zippers and inserting and turning keys in locks.

Peripheral neuropathies that involve nerve roots (polyradiculopathies, such as acute inflammatory demyelinating polyradiculoneuropathy, the most common cause of the Guillain-Barré syndrome) usually cause proximal muscle weakness that results in difficulty arising from a chair, climbing stairs, or working with the arms over the head (e.g., washing or combing hair). Positive motor symptoms, which are less common, include cramps and fasciculations, which are characteristic of disorders involving the motor neuron (e.g., amyotrophic lateral sclerosis) but also may be seen in peripheral neuropathies.

Careful examination of deep tendon reflexes is an important part of the clinical examination. Absence of reflexes often reflects a demyelinating neuropathy. In patients with acute numbness or weakness, this finding suggests Guillain-Barré syndrome. Length-dependent reduction or loss of reflexes (e.g., in Achilles tendons) is common in peripheral polyneuropathies. Because both the afferent and efferent limbs of the deep tendon reflexes involve large myelinated fibers, reflexes are often normal in neuropathies that preferentially involve small-diameter lightly myelinated and unmyelinated axons.

Autonomic symptoms (Chapter 386) are frequent in neuropathies associated with diabetes (Chapter 210) or amyloidosis (Chapter 174) and include urinary retention or incontinence, abnormalities of sweating, constipation alternating with diarrhea, and lightheadedness when standing. Erectile dysfunction is frequent in men.

DIAGNOSIS

A Systematic Approach to Patients with Neuropathy

Diagnosis of peripheral neuropathies is founded on neuroanatomical localization (Table 388-1).[1] The pattern of involvement is often appreciable with a careful history. The most common form of neuropathy is peripheral polyneuropathy. Polyneuropathies cause length-dependent, "stocking glove" symptoms and signs. Most polyneuropathies are sensory predominant, although some forms, particularly inherited polyneuropathies, cause more weakness than sensory loss. Multifocal and asymmetrical distal predominant motor and sensory signs and symptoms usually suggest a disorder involving multiple individual peripheral nerves ("mononeuritis multiplex"). Polyradiculopathies, which involve multiple nerve roots, cause non–length-dependent motor and sensory signs and symptoms that involve both proximal and distal locations. Recognition of a specific pattern can suggest a diagnosis. For example, a patient with stepwise development of asymmetrical distal weakness, pain, and numbness likely has a mononeuritis multiplex, which is usually caused by a vasculitis (Chapter 249).

Approximately 50% of patients with an acquired peripheral polyneuropathy have diabetes (Chapter 210), and most of the remainder have cryptogenic sensory peripheral neuropathy. Over half of patients with cryptogenic sensory peripheral neuropathy have prediabetes or previously unrecognized mild diabetes, and up to 80% have the metabolic syndrome. Every patient with this pattern of polyneuropathy should be evaluated for diabetes and prediabetes, paraproteinemia (Chapter 173), and vitamin B_{12} deficiency (Chapter 199). In the absence of clinical evidence of a systemic disorder or history of toxic exposure associated with peripheral polyneuropathy (Table 388-2), additional diagnostic evaluation is usually unhelpful.

Disorders of the peripheral nervous system usually conform to one of ten patterns, which reflect the underlying neuroanatomic pattern of impairment of sensory, motor, and/or autonomic function caused by the specific disorder. Recognition of a specific pattern narrows the differential diagnosis and focuses the diagnostic evaluation (Table 388-3).

Any pattern other than typical neuropathy, or the presence of any atypical "red flag" (e.g., an acute onset suggestive of inflammatory, infectious, or toxic causes; proximal involvement; motor predominance; significant ataxia; or asymmetry), should prompt additional diagnostic evaluation to assess the neuroanatomic localization, underlying physiology (demyelinating versus axonal), and structural changes (Fig. 388-1).

Nerve Conduction Studies and Electromyography

Nerve conduction studies and electromyography (Chapter 366) should be performed in all patients with diagnostic red flags or patterns other than distal, symmetrical, sensory-predominant polyneuropathy. On nerve conduction studies, axonal polyneuropathies reduce the action potential amplitudes of sensory nerves and, if there is motor axonal involvement, muscle action potential amplitudes as well; however, conduction velocities and latencies remain normal. Demyelinating neuropathies slow conduction velocities and prolong distal latencies. Genetic demyelinating polyneuropathies cause uniform conduction slowing, but acquired demyelinating neuropathies cause nonuniform slowing.

On electromyography, abnormal insertional and spontaneous activity, such as fibrillations or positive sharp waves, suggests acute or active axon injury. The presence of large, polyphasic motor units suggests partial reinnervation of muscle by regenerating axons (i.e., a more chronic process). Recruitment of motor units (firing too few motor units at a higher than normal frequency) is reduced in patients with demyelinating and axonal neuropathies.

Nerve and Skin Biopsy

The most common indications for biopsy of a distal sensory nerve, usually the sural or superficial peroneal sensory nerve, is peripheral nerve vasculitis (Fig. 388-2). Among patients referred for suspected peripheral nerve vasculitis, a simultaneous muscle biopsy increases diagnostic yield from approximately 50% to 60 to 70%. The second most common indication for nerve biopsy is evaluation for suspected light chain amyloidosis (Chapter

TABLE 388-1 TYPES OF NEUROPATHIES

PERIPHERAL NERVOUS SYSTEM LOCALIZATION	SYSTEMS INVOLVED	ANATOMIC DISTRIBUTION	EXAMPLES
Acquired peripheral polyneuropathy	Positive sensory symptoms and sensory signs; usually less motor involvement	Symmetrical and length dependent ("stocking glove") sensory loss and weakness	Diabetes, cryptogenic sensory peripheral neuropathy, chemotherapy-induced peripheral neuropathy
Genetic peripheral polyneuropathy	Motor often greater than sensory, with primarily negative sensory symptoms (numbness), high arched feet, and hammer toes	Symmetrical and length-dependent ("stocking glove") weakness and sensory loss	Charcot-Marie-Tooth disease
Mononeuritis multiplex	Motor and sensory, often painful	Asymmetrical, usually distal predominant	Vasculitis (systemic and primary peripheral nervous system)
Polyradiculopathy	Motor greater than sensory involvement	Proximal and distal; usually symmetrical but may be asymmetrical	Acute or chronic inflammatory demyelinating polyradiculoneuropathy (symmetrical); diabetic radiculoplexus neuropathy (asymmetrical)
Sensory neuronopathy (dorsal root ganglionopathy)	Sensory only, usually with ataxia and often painful	Proximal and distal, and asymmetrical	Sjögren syndrome, paraneoplastic (anti-Hu), idiopathic

174).[2] Nerve masses usually require a biopsy to diagnose a potential tumor. Rarely, nerve biopsy may be useful in the diagnosis of other infiltrative or inflammatory disorders.

Skin biopsies are routinely performed to confirm the presence of a small fiber neuropathy in patients with distal symmetrical sensory loss with neuropathic pain (Fig. 388-3), in which nerve conduction studies are usually normal, with an antibody that binds to all axons (PGP 9.5). The diagnosis of small fiber neuropathy is based on demonstrating a reduced density of intraepidermal nerve fibers.

Laboratory Testing

A hemoglobin A_{1c} level is usually the best first test in all patients with distal symmetrical polyneuropathy, but 2-hour glucose tolerance may be performed when the suspicion for prediabetes is high (Chapter 210). Paraproteinemia is most easily evaluated by measuring serum globulin levels and performing a serum protein electrophoresis (Chapter 173). The vitamin B_{12} level should also be measured; if it is borderline, a methylmalonic acid level may be required to confirm deficiency. Other common disorders associated with polyneuropathy include hepatitis C (Chapter 135) and HIV (Chapter 359). Heavy alcohol users (Chapters 364 and 384) are also at risk for polyneuropathy owing to a combination of direct ethanol toxicity and associated vitamin deficiency, particularly vitamin B_1 (thiamine).

TABLE 388-2 SELECTED CAUSES FOR TOXIC NEUROPATHIES

TOXIN CATEGORY	SPECIFIC AGENTS
Antineoplastic agents	Paclitaxel, cisplatin, oxaliplatin, bortezomib, thalidomide
Antimicrobials	Chloroquine, dapsone, isoniazid, metronidazole, nitrofurantoin
Cardiac medications	Amiodarone, perhexiline, hydralazine
Other medications	Colchicine, gold salts, phenytoin, disulfiram, pyridoxine
Heavy metals	Lead (wrist drop), arsenic, thallium (alopecia), mercury
Organic solvents	Hexane, acrylamide, vacor

In selected patients, electrodiagnostic studies will suggest the need to test for specific antibodies, such as antibodies reacting to ganglioside GM_1 (multifocal motor neuropathy) or myelin-associated glycoprotein (MAG—distal demyelinating neuropathy with weakness and tremor).[3] Genetic testing is most cost-effective when the selection of candidate genes is based on the patient's nerve conduction studies, inheritance pattern, and clinical findings.

INHERITED NEUROPATHIES

Inherited neuropathies can be divided into those that affect the peripheral nervous system in isolation, such as Charcot-Marie-Tooth (CMT) disease, and those that involve multiple organ systems.

CHARCOT-MARIE-TOOTH DISEASE

EPIDEMIOLOGY AND PATHOBIOLOGY

Charcot-Marie-Tooth disease has a prevalence of 1 : 2500 and is caused by mutations that affect myelin formation. Autosomal dominant Charcot-Marie-Tooth is subdivided into demyelinating (CMT1) and axonal (CMT2) forms based on electrophysiologic criteria. Many patients have de novo mutations. X-linked (CMTX) and autosomal recessive demyelinating (CMT4) and axonal (CMT-AR2) forms are also seen. Each type is further subdivided by the specific genetic cause. The most common form, CMT1A, is caused by a duplication of a fragment of chromosome 17 containing the peripheral myelin protein 22-kD *(PMP22)* gene. The most common form of CMT2 is a mutation in the mitofusin gene (CMT2A). Overall, CMT1A accounts for roughly 50% of all cases of Charcot-Marie-Tooth disease, CMT1X accounts for 10 to 20%, CMT1B for less than 5%, and CMT2 for 20%. However, mutations have been identified in more than 100 genes, and this number is likely to increase substantially in the future.

CLINICAL MANIFESTATION

Classic Charcot-Marie-Tooth disease causes slowly progressive distal weakness and sensory loss, often beginning in the first 2 decades of life, but an increasing number of patients are being identified well into adulthood and even in later years of life.[4] Children are often slow runners and have impaired balance (e.g., skating, walking across a log). Ankle-foot orthoses are frequently required by the third decade. Fine hand movements (e.g., fastening jewelry, turning a key, or using buttons and zippers) may be impaired. Most patients have distal leg atrophy (inverted champagne bottle) with high arched feet (pes cavus) and hammer toes (Fig. 388-4). Nevertheless, many patients remain ambulatory

TABLE 388-3 TEN TYPICAL PATTERNS OF NERVOUS SYSTEM DISORDERS

ANATOMIC PATTERN	NEUROANATOMIC LOCALIZATION	DIFFERENTIAL DIAGNOSIS
1. Symmetrical proximal and distal weakness with sensory loss	Polyradiculoneuropathy	Acute inflammatory demyelinating polyradiculoneuropathy if acute and maximal involvement within the first 4 weeks, chronic inflammatory demyelinating polyneuropathy if progressive over >8 weeks
2. Symmetrical distal sensory loss with or without distal weakness	Peripheral polyneuropathy	Cryptogenic sensory peripheral neuropathy, diabetes or other metabolic disorders, toxic, hereditary such as Charcot-Marie-Tooth
3. Asymmetrical distal weakness with sensory loss	Mononeuritis multiplex	Vasculitis, hereditary neuropathy with predisposition to pressure palsies, multifocal acquired demyelinating sensory and motor neuropathy, infections (e.g., leprosy)
	Mononeuropathy or radiculopathy	Compression, trauma, or tumor
4. Asymmetrical proximal and distal weakness with sensory loss	Polyradiculopathy	Polyradiculopathy or plexopathy due to diabetes (diabetic lumbosacral radiculoplexus neuropathy) or a meningeal disorder (carcinoma, lymphoma, sarcoidosis, chronic infection)
5. Asymmetrical distal weakness without sensory loss	Motor neuronopathy with upper motor neuron signs (brisk reflexes, spasticity, Babinski responses)	Amyotrophic lateral sclerosis Progressive muscular atrophy, multifocal motor neuropathy, monomelic amyotrophy (Hirayama disease)
	Motor neuronopathy (lower motor neurons) or motor neuropathy	
6. Symmetrical sensory loss with distal areflexia with upper motor neuron findings	Mixed myelopathy and polyneuropathy	Severe combined degeneration due to vitamin B_{12} or copper deficiency or to inherited disorders (adrenomyeloneuropathy, metachromatic leukodystrophy, Friedreich ataxia)
7. Symmetrical weakness without sensory loss	Motor neuronopathy	Proximal and distal: spinal muscular atrophy or progressive muscular atrophy
	Motor neuropathy	Distal predominant: hereditary motor neuropathy
8. Focal midline proximal weakness	Motor neuronopathy, neuromuscular junction disorder, myopathy	Neck extensor weakness (head drop): amyotrophic lateral sclerosis, myasthenia gravis, myopathy
		Bulbar weakness: amyotrophic lateral sclerosis, myasthenia gravis
9. Asymmetrical sensory loss with sensory ataxia without weakness	Sensory neuronopathy/ganglionopathy	Sjögren, paraneoplastic (anti-Hu antibody), idiopathic
	Sensory polyradiculoneuropathy	Chronic immune sensory polyradiculoneuropathy
10. Autonomic symptoms and signs	Autonomic neuropathy	Diabetes, amyloid, autoimmune autonomic neuropathies

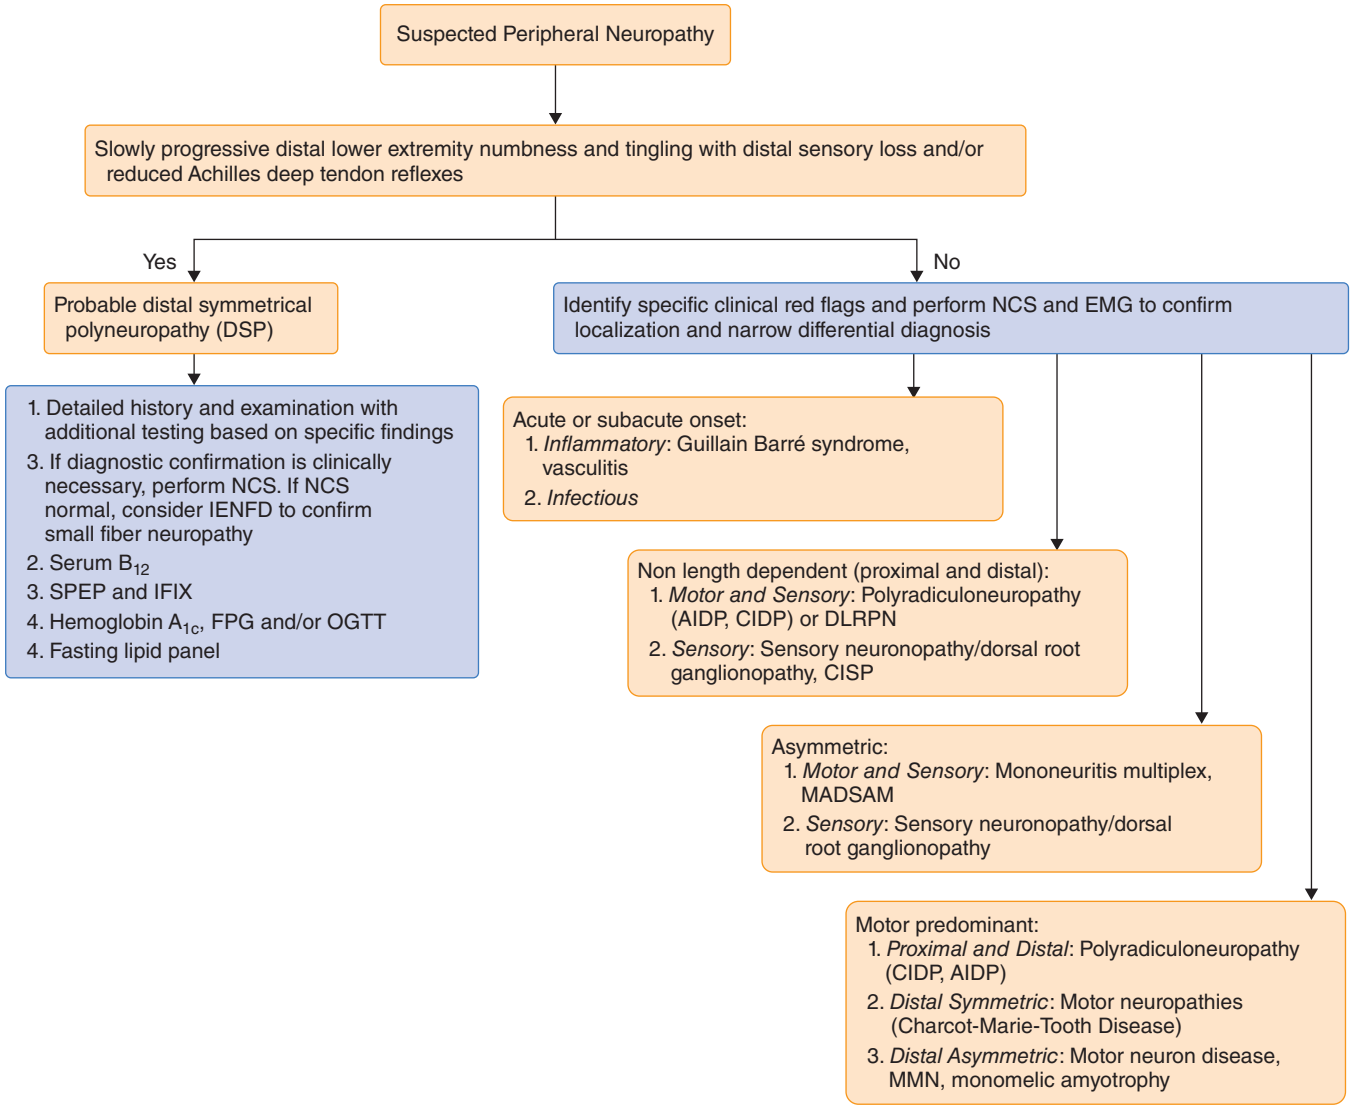

FIGURE 388-1. Diagnostic flow diagram for suspected peripheral neuropathy. AIDP = acute inflammatory demyelinating polyradiculoneuropathy; CIDP = chronic inflammatory demyelinating polyradiculoneuropathy; CISP = chronic inflammatory sensory polyradiculoneuropathy; DLRPN = diabetic lumbosacral radiculoplexus neuropathy ("diabetic amyotrophy"); DSP = distal symmetric polyneuropathy; EMG = electromyography; FPG = fasting plasma glucose; IENFD = intraepidermal nerve fiber density; IFIX = immunofixation; MADSAM = multifocal acquired demyelinating sensory and motor neuropathy; MMN = multifocal motor neuropathy; NCS = nerve conduction studies; OGTT = oral glucose tolerance test; SPEP = serum protein electrophoresis.

throughout life, and most have a normal lifespan. A minority of patients have a more severe phenotype with delayed motor milestones and onset in infancy (Dejerine-Sottas neuropathy).

Patients with hereditary motor neuropathies sometimes have mild sensory abnormalities, and patients with hereditary sensory and autonomic neuropathies usually have some weakness. The extent of motor or sensory loss can sometimes alter the classification. For example, the same mutations in the same gene (*GARS*) may cause both CMT2D and hereditary motor neuropathy type V (Video 388-1).

DIAGNOSIS

Genetic testing is the gold standard for accurately diagnosing patients with inherited neuropathies, but it should be combined with a careful family history, clinical examination, and neurophysiologic testing. The diagnostic yield of genetic testing is highest among patients with clinical onset at a young age and a positive family history. For CMT1A, which comprises about 50% of cases of Charcot-Marie-Tooth disease, genetic testing must specifically search for a PMP22 duplication, which will not be diagnosed by next-generation sequencing. If this test is negative or in patients with axonal variants (CMT2), next-generation sequencing is typically performed. Since not all variants are pathogenic and many are described as variants of uncertain significance, it is essential to determine, if possible, whether a given variant tracks with neuropathy in a family, whether the variant is common in population databases, and whether it is predicted to be pathogenic in animal or *in silico* models.

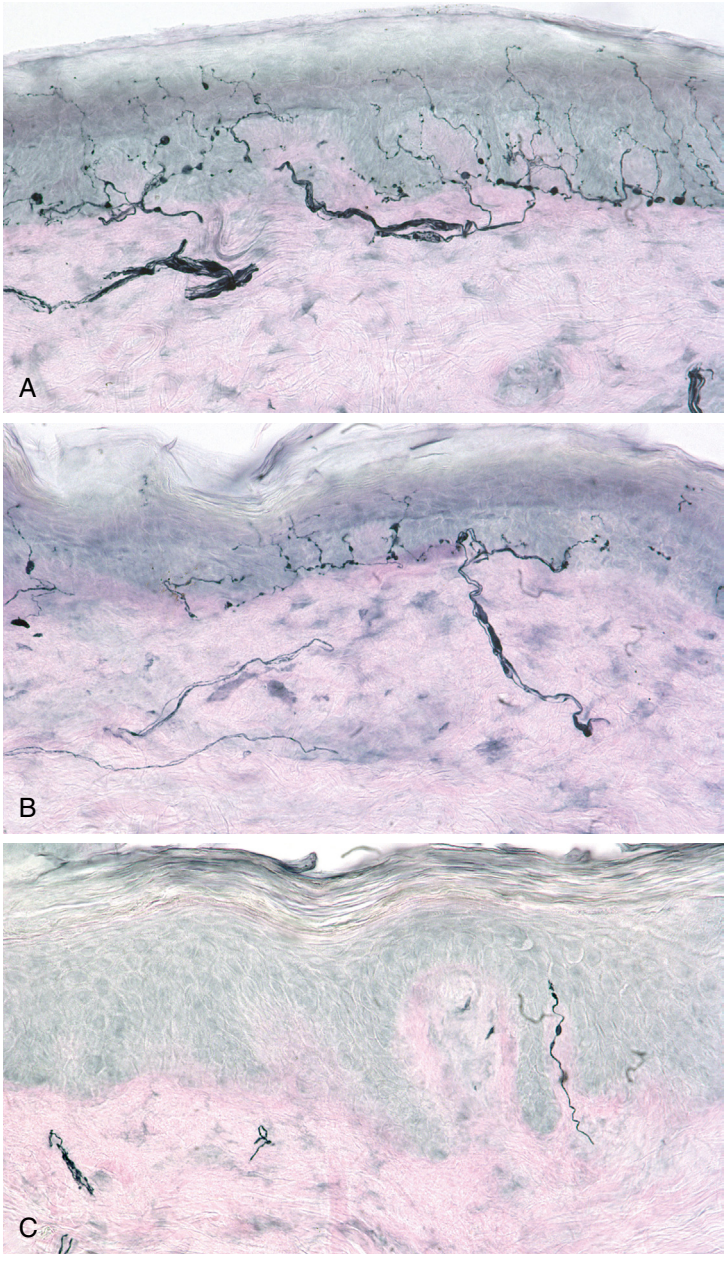

FIGURE 388-3. Skin biopsies from the proximal thigh (A), distal thigh (B), and distal leg (C) of a patient with suspected small fiber neuropathy were stained with PGP 9.5, a pan-axonal marker.

Differential Diagnosis

Inherited neuropathies must be distinguished from acquired neuropathies. Clinical clues that a neuropathy is likely to be genetically based are slow progression beginning in early childhood, abnormal foot structure, and uniform slowing of upper extremity nerve conduction velocities in CMT1. CMT2 is characterized by axonal loss as reflected by reduced compound muscle action potential and sensory nerve action potential amplitudes. Other genetic disorders, such as hereditary spastic paraplegia (Chapter 379) or leukodystrophies (Chapter 380), may mimic inherited neuropathies by causing distal weakness, sensory loss, and foot deformities such as pes cavus; these patients often have upper motor neuron signs and may have clinical and neurophysiologic evidence of neuropathy.

TREATMENT

Ankle-foot orthoses may return gait and balance to normal for years. Foot surgery to correct inverted feet, pes cavus, and hammer toes can sometimes improve walking, alleviate pain over pressure points, and prevent plantar ulcers. Experimental molecular treatments are emerging for inherited neuropathies. For example, antisense oligonucleotides and RNA inhibition have proven effective in mouse and rat models.

FIGURE 388-4. Distal leg atrophy and high arched feet (pes cavus) in a patient with Charcot-Marie-Tooth disease.

PROGNOSIS

A detailed family history and examination of family members may be required for prognosis and genetic counseling. In general, Charcot-Marie-Tooth is a slowly progressive disorder that does not affect longevity, although many patients experience progressive gait difficulties with aging. The prognosis and degree of disability vary among specific forms.

FAMILIAL AMYLOID POLYNEUROPATHY

Familial amyloid polyneuropathy (Chapter 174) is caused by dominantly inherited mutations in one of at least three genes: transthyretin, apolipoprotein A1, and gelsolin. Pathogenic mutations in transthyretin cause a conformational change that destabilizes its normal tetramers, thereby resulting in intracellular aggregates that form amyloid deposits in peripheral nerve, heart, and other tissues.

Familial amyloid polyneuropathy typically presents as a painful sensory neuropathy in mid to late adulthood, with prominent autonomic features, including sexual dysfunction, gastrointestinal disturbances, and cardiac arrhythmias, followed by weakness, weight loss, and inanition. Certain mutations commonly cause neuropathy (Val30Met), whereas others (Val122Ile) usually present with heart disease.

Diagnosis is based on genetic testing supported by tissue evidence of amyloid because mutations are not always penetrant.[5]

TREATMENT

Tafamidis (20 mg daily) acts to stabilize the variant transthyretin polymer to prevent its dissociation and can delay progression of the polyneuropathy.[A1] Other effective options for polyneuropathy include patisiran (a small interfering RNA at 30 mg intravenously every 3 weeks)[A2] and inotersen (an antisense oligonucleotide at 284 mg subcutaneously weekly).[A3] Diflunisal (250 mg twice daily), which is a generic nonsteroidal anti-inflammatory drug that complexes to the thyroxine binding sites on the tetrameric form of transthyretin, stabilizes it, and thus inhibits the release of the transthyretic monomer required for amyloidogenesis, can slow the rate of progression of familial amyloidosis-associated polyneuropathy.[A4] Gene editing using clustered regularly interspaced short palindromic repeats and associated Cas9 endonuclease (CRISPR-Cas9) is an experimental approach to lowering the transthyretin protein concentration.

PROGNOSIS

Death has typically occurred within a decade of diagnosis owing to cardiac or autonomic failure unless patients underwent liver transplantation. As noted earlier, however, new molecular therapies, including inotersen and patisiran, can substantially slow progression, with their long-term benefits still to be determined.

INFLAMMATORY AND IMMUNOLOGIC NEUROPATHIES

Autoimmune disorders of the peripheral nervous system include primary inflammatory neuropathies (Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy) as well as neuropathies related to vasculitis and other systemic autoimmune disorders.

GUILLAIN-BARRÉ SYNDROME

DEFINITION

Guillain-Barré syndrome refers to acquired, inflammatory polyradiculoneuropathies that share an acute onset, elevated cerebrospinal fluid (CSF) protein levels with low cell counts (cytoalbuminologic dissociation), and a monophasic course.[6] Guillain-Barré syndrome is subdivided into demyelinating (acute inflammatory demyelinating polyradiculoneuropathy), and axonal (acute motor and sensory axonal neuropathy and acute motor axonal neuropathy) variants, and the Miller-Fisher syndrome.

EPIDEMIOLOGY

The annual incidence of Guillain-Barré syndrome is 1 to 2 per 100,000, although in some areas the incidence may be higher. Acute inflammatory demyelinating polyradiculoneuropathy accounts for 97% of cases in North America and Europe with an incidence of 0.6 to 1.9 cases per 100,000. Men are more often affected than women (1.4 : 1). In 60% of patients, a respiratory tract infection or gastroenteritis precedes Guillain-Barré syndrome. Patients with axonal variants are particularly likely to have had a prior *Campylobacter jejuni* diarrheal illness.[7] In Belgium and the Netherlands, 5 to 10% of patients have a preceding hepatitis E infection (Chapter 134), thereby emphasizing the regional variability in infectious triggers. Guillain-Barré syndrome does not appear to be substantially associated with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection or vaccination (Chapters 335 to 337), aside from a slight increase in risk of 0.6 cases/100,000 doses for the ChADOx1nCoV-19 vaccine,[8] and the incidence of Guillain-Barré syndrome actually declined during the pandemic likely due to a reduced incidence of communicable diseases known to provoke Guillain-Barré syndrome.[9] In contrast, Zika virus (Chapter 352) has been associated with a significantly increased risk of all forms of Guillain-Barré syndrome,[10] as well as a transient polyneuritis pattern of mild distal sensory symptoms (acute peripheral polyneuropathy).

PATHOBIOLOGY

All forms of Guillain-Barré syndrome probably result from postinfectious molecular mimicry, in which the immune system attacks peripheral nerve antigens because they resemble antigens presented by microbes, in particular, *C. jejuni*. For example, the HS/0:19 serotype of *C. jejuni* is common in patients with the acute motor axonal neuropathy form of Guillain-Barré syndrome in northern China and other countries. However, it is not clear that molecular mimicry causes acute inflammatory demyelinating polyradiculoneuropathy, which is the most common form in the United States and Europe.

CLINICAL MANIFESTATIONS

Weakness is the most common initial symptom. It can be mild, such as difficulty walking, or severe, with total quadriplegia and respiratory failure. The most common manifestation is leg weakness that progresses into the arms. Bilateral facial weakness occurs in 50% of patients and may lag behind limb weakness. Although Guillain-Barré syndrome has been described as an "ascending paralysis," proximal weakness is common, and 5% of patients have isolated cranial nerve involvement that subsequently descends into the limbs. Slight sensory loss occurs in most patients. The autonomic nervous system is involved in about 65% of cases.

Acute motor sensory axonal neuropathy is clinically similar to acute inflammatory demyelinating polyradiculoneuropathy except it is typically more severe because of primary injury to axons rather than to myelin. Autonomic dysfunction is more common. Weakness without sensory loss develops in acute motor axonal neuropathy, including cranial nerve involvement in about 25% of patients.

The Miller-Fisher syndrome consists of the triad of ophthalmoplegia, ataxia, and areflexia. Facial weakness, ptosis, and pupillary abnormalities may be present. Nerve conduction velocities in Miller-Fisher syndrome are normal, unlike acute inflammatory demyelinating polyradiculoneuropathy.

DIAGNOSIS

The diagnosis of acute inflammatory demyelinating polyradiculoneuropathy and acute motor sensory axonal neuropathy is based on the history, physical examination, CSF evaluation, and nerve conduction studies.[11] Weakness is symmetrical, and deep tendon reflexes are decreased or absent. The presence of other CNS abnormalities should cast doubt on the diagnosis.

CSF analysis typically reveals high protein with a paucity of white blood cells (WBCs). The CSF should have fewer than 5 WBCs/mL; a CSF cell count greater than 50 WBCs/mL suggests HIV seroconversion (Chapters 355 and 359) or infections such as Lyme disease (Chapter 296). Acute inflammatory demyelinating polyradiculoneuropathy is distinguished from acute motor sensory axonal neuropathy by nerve conduction studies. Because elevated CSF protein and abnormal nerve conduction studies may not be apparent in the first 7 to 10 days of the illness and because CSF protein remains normal in up to 10% of cases, the initial treatment decision often must be made based on clinical judgment. Most Miller-Fisher syndrome patients (>85%) have polyclonal antibodies that react to the ganglioside GQ_{1b}.

Differential Diagnosis

Guillain-Barré syndrome usually causes symmetrical proximal and distal weakness with milder sensory loss that reaches maximum severity in less than 4 weeks. A number of warning signs suggest further evaluation for an alternative diagnosis (Table 388-4). Other causes for symmetrical acute weakness include acute toxic neuropathies; fulminant myopathies, particularly immune-mediated necrotizing myopathy (the serum creatine kinase level is usually markedly elevated); and myasthenia gravis (ptosis, diplopia and dysphagia/dysarthria; Chapter 390). Botulism (Chapter 271) causes ophthalmoplegia, unreactive pupils, bulbar weakness, dry mouth, constipation, and orthostatic hypotension, without sensory symptoms. Asymmetrical weakness can be seen with viral encephalomyelitis (Chapter 383). In North America, polio has been eradicated, but other viral illnesses may induce polio-like syndromes including ECHO 70, coxsackievirus (Chapter 349), and West Nile virus (Chapter 352). Though very rare, rabies (Chapter 383) also may present with rapidly progressive paralysis. Tick paralysis, caused by a toxin within the tick, can mimic Guillain-Barré syndrome, particularly in children. Usually, removal of the tick is associated with improvement within hours, although progression can occur, particularly in Australia, where the toxin differs from that found in North America.

Acute myelopathies such as transverse myelitis (Chapter 380), neuromyelitis optica (Chapter 392), and vascular myelopathies (Chapter 248) may also cause rapidly progressive symmetrical weakness and sensory loss. Brisk reflexes and a sensory level are often observed, and bowel and bladder dysfunction are apparent. Carcinomatous or lymphomatous meningitis can also cause a rapidly developing quadriparesis owing to an acute polyradiculopathy.

Nerve conduction studies and electromyography are helpful in excluding myopathies and disorders of the neuromuscular junction. Other acute neuropathies cause axonal injury, so neurophysiologic findings share features with axonal variants of Guillain-Barré syndrome. CSF analysis can be helpful in excluding infectious causes.

TREATMENT

Patients with Guillain-Barré syndrome require hospitalization because of the risk of respiratory compromise, and the decision to admit a patient to an intensive care unit should be based on the trajectory of change in respiratory function and clinical assessment. A vital capacity of less than 1 L or a negative inspiratory force of less than −70 cm water suggests the need for ventilator support (Chapter 91) in an intensive care unit. Autonomic and swallowing function should also be monitored. Guillain-Barré syndrome can be treated within 2 weeks of onset with either intravenous immunoglobulin (IVIG, 2g/kg divided over 2 days or longer if necessary because of the patient's cardiac function or fluid status) or therapeutic plasma exchange of 5 plasma volumes over 10 days.[A5] Patients are significantly more likely to complete a full course of IVIG, so this treatment is generally preferred. Methylprednisolone (500mg/day for 5 days) plus IVIG has a slight initial advantage but no long-term benefit compared with IVIG alone;[A6] given its risks, it generally is not recommended. A second dose of IVIG does not improve outcomes, is associated with a higher risk of complications, and should not be given.[A7] The prognosis of Miller-Fisher syndrome is generally excellent, and there is controversy regarding the necessity of treatment with IVIG or plasma exchange

TABLE 388-4 WARNING SIGNS SUGGESTING AN ALTERNATIVE DIAGNOSIS IN PATIENTS WITH SUSPECTED GUILLAIN-BARRÉ SYNDROME

WARNING SIGN	DIFFERENTIAL DIAGNOSIS
Sensory predominant	Sensory neuronopathy
Prominent bowel and bladder symptoms	Myelopathy
Spinal sensory level	Myelopathy
Persistently asymmetrical weakness	Viral encephalomyelitis (enteroviral), mononeuritis multiplex (vasculitis), radiculoplexus neuropathy (diabetic amyotrophy)
Distal predominant weakness and sensory loss (peripheral polyneuropathy pattern)	Toxic neuropathies (e.g., arsenic)
Slow progression	Chronic inflammatory demyelinating polyradiculoneuropathy
CSF: >50 WBCs/μL	HIV seroconversion

CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; WBC = white blood cell.

PROGNOSIS

Fifty percent of patients progress to maximum disability within 2 weeks of the onset of symptoms, 75% within 3 weeks, and greater than 90% within 4 weeks. With supportive care, mortality is 3% at 6 months, primarily in the elderly and severely affected patients, and especially during the recovery phase. After a brief period of stabilization, slow recovery occurs over weeks to months. Most patients recover completely or are left with minor sequelae; 20% have a persistent disability. The prognosis is poorer in patients who present with weakness, have axonal variants, or have acute inflammatory demyelinating polyradiculoneuropathy with significant axonal loss as reflected by reduced compound muscle action potential amplitudes in the upper extremities. Other predictors of a poor prognosis include older age, preceding diarrheal illness, and the severity of weakness.

CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

DEFINITION

Chronic inflammatory demyelinating polyradiculoneuropathy is usually slowly progressive but may be monophasic or relapsing. By definition, it develops over at least 2 months and more slowly than acute inflammatory demyelinating polyradiculoneuropathy, which it otherwise resembles.

EPIDEMIOLOGY

Chronic inflammatory demyelinating polyradiculoneuropathy[12] occurs in all age groups, with a mean age of 30 to 50 years. Women are more likely to be affected. Antecedent events in about 30% of patients include upper respiratory infections, gastrointestinal infections, vaccinations, surgery, and trauma. In some patients it is a paraneoplastic phenomenon, especially with non-Hodgkin lymphoma (Chapter 171).[13]

PATHOBIOLOGY

Chronic inflammatory demyelinating polyradiculoneuropathy is considered an autoimmune disorder based on its pathology and experimental models, in which a similar disorder follows immunization with peripheral nervous system myelin components and Freund adjuvant. Nerve biopsy shows macrophage-mediated segmental demyelination, occasional endoneurial lymphocytic T-cell infiltrates, and endoneurial edema. Major histocompatibility complex class I and II antigens are upregulated, and there are often deposits of immunoglobulins and complement on the outer Schwann cell membranes or myelin sheaths. Chronic inflammatory demyelinating polyradiculoneuropathy can be passively transferred to animals by patient sera, but no clear autoantigen has been identified.

CLINICAL MANIFESTATIONS

Weakness and sensory loss begin insidiously and progress over a period of months to years. Weakness, which involves both proximal and distal muscles, is usually symmetrical. The absence of proximal weakness suggests a polyneuropathy. Patients often require assistance with ambulation. Loss of proprioception from damage to large-diameter sensory nerves may affect balance. Deep tendon reflexes are usually absent or markedly decreased. Facial weakness (15%), ptosis, or ophthalmoparesis (5%) may occur. Variants include pure motor, pure sensory, and multifocal forms (multifocal acquired demyelinating sensory and motor neuropathy).

DIAGNOSIS

Diagnosis is based on clinical symptoms and signs, CSF examination, and electrodiagnostic studies.[14] CSF results resemble those of acute inflammatory demyelinating polyradiculoneuropathy: WBC counts are usually fewer than 10 cells/μL, and the level of protein is greater than 60 mg/dL. A CSF WBC count greater than 50/μL suggest another diagnosis, such as HIV infection or hematologic malignancy.

Nonuniform, asymmetrical slowing of motor nerve conduction velocity with prolonged minimal F wave latencies is typical. Compound muscle action potential amplitudes are generally reduced because of secondary axonal degeneration. Sensory nerve action potential amplitudes are usually reduced or absent.

Many patients, however, do not meet formal electrophysiologic criteria for chronic inflammatory demyelinating polyradiculoneuropathy. The combination of symmetrical onset of weakness involving all four limbs with proximal weakness in at least one limb has a comparable diagnostic accuracy (sensitivity 83%, specificity 97%).

A subset of patients with severe disability, subacute onset, tremor, sensory ataxia, and poor response to IVIG have antibodies reactive against contactin or neurofascin.[15] These antibodies, which are usually of the immunoglobulin (Ig) G4 isotype, bind to the nodal and paranodal region.

Differential Diagnosis

Chronic inflammatory demyelinating polyradiculoneuropathy, which is distinguished from acute demyelinating polyneuropathy by its time course, may be associated with monoclonal gammopathies (Chapter 173). However, it does not appear to be related to diabetes.

Different clinical patterns should suggest a broader differential diagnosis, and up to 50% of patients initially diagnosed with chronic inflammatory demyelinating polyneuropathy may be incorrectly diagnosed. Overdiagnosis is often related to misinterpretation of nerve conduction study data, a mild to moderate elevation of CSF protein, or reliance on a subjective response to immunotherapy rather than on objective evidence of improvement.[16]

TREATMENT

A standard approach is oral prednisone (1 mg/kg/day) for 6 to 8 weeks, followed by slow tapering over a 3- to 12-month period to a maintenance level of about 0.1 mg/kg/day.[A8] A response to prednisone may take months to occur, and occasional patients may worsen before they respond. Other alternatives are pulsed dexamethasone (6 cycles of 40 mg/day orally for 4 days) or short-term prednisolone (60 mg/day for 5 weeks, then tapering to zero). IVIG at a dose of 1 g/kg every 3 weeks is also effective. Most patients respond within the first three treatments, and a failure to do so suggests a low likelihood of future response. IVIG is more frequently effective than corticosteroids initially, but it may have a less durable benefit. Subcutaneous injections of immunoglobulin are another therapeutic option. Although plasma exchange also is effective, it is difficult to use as a chronic therapy. Because of the side effects of long-term corticosteroids, azathioprine 2 mg/kg and mycophenolate mofetil 1000 to 1500 mg in divided doses twice daily are often used as steroid-sparing agents.

Patients with contactin or neurofascin antibodies may respond to corticosteroids or IVIG; however, these patients may respond better to rituximab, often administered at a dose of 325 mg/m^2 weekly for four doses. New therapeutic agents under active investigation include inhibitors of FcRn (neonatal Fc receptor) and complement.

MULTIFOCAL MOTOR NEUROPATHY

DEFINITION

Multifocal motor neuropathy is characterized by progressive, distal more than proximal, asymmetrical limb weakness, mostly affecting the upper limbs with minimal or no sensory impairment.

EPIDEMIOLOGY

The prevalence of multifocal motor neuropathy is estimated at 2 per 100,000. Men are more frequently affected than women (2.6 : 1). Initial symptoms develop in 80% between 20 and 50 years, with a mean age at onset of 40 years.

PATHOBIOLOGY

Multifocal motor neuropathy is considered to be an autoimmune neuropathy based on clinical improvement with immunotherapies and because patients often have serum antibodies that react with ganglioside GM_1 and because this antibody titer decreases during effective treatment. GM_1 is highly represented in neural membranes at the nodes of Ranvier, compact myelin, and the motor end plate at the neuromuscular junction.

CLINICAL MANIFESTATIONS

The usual pattern is progressive, distal, asymmetrical arm weakness, often in the distribution of a single nerve. In a minority of patients, weakness may start proximally or in the legs. Multifocal motor neuropathy frequently affects multiple nerve distributions, occasionally with a crossed distribution (i.e., one arm and the contralateral leg). Asymmetry and predominance of arm weakness may become less evident over time. Localized muscle atrophy, which may be mild or absent initially, becomes prominent later as a result of axonal degeneration.

DIAGNOSIS

The diagnosis is established by the presence of multifocal, persistent, partial conduction block on motor but not sensory nerve conduction studies. Conduction block can be hard to find, however, and multifocal motor neuropathy should be considered in patients with a typical clinical pattern in the absence of upper motor neuron signs. Anti-GM_1 ganglioside antibodies are detectable in 50% of patients with multifocal motor neuropathy.

Differential Diagnosis

Multifocal motor neuropathy shares many diagnostic features with amyotrophic lateral sclerosis (Chapter 387), including distal asymmetrical upper extremity weakness and atrophy. Key differentiating features include the time course (multifocal motor neuropathy is slowly progressive whereas amyotrophic lateral sclerosis progresses rapidly) and the absence of respiratory or bulbar weakness and of upper motor neuron features. Magnetic resonance imaging or ultrasound of peripheral nerve may be useful in differentiating multifocal motor neuropathy without GM_1 antibodies or conduction block from amyotrophic lateral sclerosis.[17] Multifocal motor neuropathy also may be confused with multifocal chronic inflammatory demyelinating polyradiculoneuropathy, which causes sensory loss as well as motor weakness and is associated with more severe sensory abnormalities on nerve conduction studies.

TREATMENT

IVIG (2 g/kg) is the initial treatment for multifocal motor neuropathy, and almost 80% of patients respond within a week. However, improvement is typically brief (3 to 6 weeks), so repeated treatments are required indefinitely. Clinical improvement is often accompanied by a reduction or resolution of motor conduction block in some nerves, but it does not consistently correlate with a reduction in GM_1 titers. In patients who may eventually become refractory to IVIG, either pulse cyclophosphamide (1 g/m^2 monthly for 6 months) or rituximab (e.g., 375 mg/m^2 weekly for 4 weeks) have been effective in case reports. Mycophenolate and corticosteroids are ineffective.

PROGNOSIS

Long-term follow-up data of patients with multifocal motor neuropathy show impairment of hand function (reduced dexterity and grip strength) and ankle stability with reduced walking speed. Although patients have greater fatigue than age-matched control subjects, their mood, working capacity, and aerobic capacity are not affected.

VASCULITIC NEUROPATHIES

Vasculitic neuropathies typically present as a subacute painful mononeuritis multiplex with acute motor and sensory loss in multiple nerve territories.

EPIDEMIOLOGY

Systemic vasculitic neuropathy is more common than nonsystemic vasculitic neuropathy, but about 10% of patients who initially have nonsystemic peripheral nerve vasculitis ultimately develop a systemic vasculitis. Peak age at onset of both are between the ages of 40 and 70 years, but vasculitis can occur at any age. Rheumatoid arthritis (Chapter 243) evolves into systemic rheumatoid vasculitis in 5 to 15% of patients, and vasculitic neuropathy develops in about 50% of these cases. More than 50% of patients with Churg-Strauss syndrome, 40 to 50% with granulomatosis with polyangiitis (Chapter 137), 35 to 75% with polyarteritis nodosa (Chapter 249), and a majority with mixed cryoglobulinemia have neuropathy. Patients with Sjögren syndrome (Chapter 247) are often initially found to have sensory neuronopathy (ganglionopathy). By comparison, neuropathies are uncommon in systemic lupus erythematosus (Chapter 245).

PATHOBIOLOGY

In patients with mononeuritis multiplex, axonal degeneration develops as a result of nerve ischemia. Inflammation and necrosis of blood vessel walls occlude the lumen, thereby resulting in ischemic damage. Peripheral nerve vasculitides can be divided into those that affect large-diameter arterioles (75 to 300 μm), small-diameter arterioles (<40 μm), and capillaries.[18]

The immune-mediated inflammation is associated with antibody-antigen complexes that are deposited in the vessel wall. Antibodies also bind directly to endothelial cell antigens. In both circumstances, complement is activated. Chemotactic factors then recruit neutrophils, which release proteolytic enzymes and generate toxic oxygen free radicals.

The sensory neuropathy of Sjögren syndrome (Chapter 247) probably results from the infiltration of dorsal root ganglia by cytotoxic T cells. Some patients with systemic vasculitis have symmetrical neuropathies rather than mononeuritis. The pathogenesis of such cases is not defined.

CLINICAL MANIFESTATIONS

Patients typically have a relatively sudden onset of painful focal or multifocal weakness or of sensory loss. These symptoms reflect ischemia anywhere along the length of the nerves, most often in the lower extremities. Up to 30% of patients have a progressive symmetrical pattern of involvement. Patients with large arteriole systemic vasculitis often have systemic symptoms, including fatigue, myalgias, fevers, and arthralgias in addition to the organ involvement that is typical for the specific disorder (Table 388-5). For example, certain forms of vasculitis may affect cranial nerves (polyangiitis with granulomatosis and Sjögren syndrome) or cause autonomic neuropathy (Sjögren syndrome). Mononeuritis multiplex can occur in systemic vasculitis that involves other organ systems, in association with underlying viral infection, or as an organ-specific (nonsystemic) peripheral nerve vasculitis.

DIAGNOSIS

Diagnostic clues are the subacute and progressive time course, as well as the presence of distal weakness and pain. The number of nerves involved may be extensive enough to make the distinction between a multifocal and diffuse neuropathy difficult, and many patients have a mildly asymmetrical or symmetrical confluent mononeuritis multiplex.

Nerve biopsy of clinically affected sensory nerves (sural, superficial peroneal, or superficial radial) is the gold standard for diagnosis, especially because aggressive, long-term therapy may be required. Diagnostic pathologic features of vasculitis are seen in about 50% of patients referred for suspected vasculitis, including destruction of the vessel and inflammation within the vessel wall, and the addition of muscle biopsy may increase diagnostic yield to 60 to 70%. Fibrinoid necrosis, vessel wall scarring, recanalization, neovascularization, and hemosiderin are common but not essential histopathologic features (see Fig. 388-2).

Electrophysiologic findings can also suggest the diagnosis. For example, electromyography and nerve conduction studies can distinguish between mononeuritis multiplex and a symmetrical neuropathy.

Differentiation of systemic versus isolated peripheral nervous system vasculitis depends on clinical and serologic evaluation. The erythrocyte sedimentation rate is usually elevated in systemic vasculitis but is often normal in nonsystemic vasculitis. Perinuclear and cytoplasmic antineutrophil cytoplasmic antibodies (p-ANCA and c-ANCA) suggest granulomatosis with polyangiitis or eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome; Chapter 249). Hepatitis C (Chapter 135) is usually associated with cryoglobulinemia. Serum complement levels, extractable nuclear antigen, angiotensin-converting enzyme levels, serum protein electrophoresis, and HIV serology are generally indicated. CSF analysis may be needed to exclude infectious (e.g., Lyme disease; Chapter 296) or other inflammatory causes.

Differential Diagnosis

Acute or subacute mononeuritis multiplex may also result from diabetic and nondiabetic lumbosacral radiculoplexus neuropathy, which usually causes proximal greater than distal weakness in the legs, sarcoidosis (Chapter 83), Lyme disease (Chapter 296), and malignant infiltration of nerves. Multifocal

TABLE 388-5 CLINICAL AND SEROLOGIC FINDINGS OF SYSTEMIC AND NONSYSTEMIC VASCULITIS INVOLVING THE PERIPHERAL NERVOUS SYSTEM

DIAGNOSIS	SEROLOGIC FEATURES	ASSOCIATED CLINICAL FEATURES	USUAL TYPE OF NEUROPATHY	PREVALENCE OF NEUROPATHY
Rheumatoid arthritis (Chapter 243)	RF (80-90%)	Arthritis frequent; multiple organs often affected	Mononeuritis multiplex and sensorimotor neuropathy	50%
Eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome) (Chapter 249)	c-ANCA (<30%), p-ANCA (<50%), eosinophilia (100%), elevated ESR (85%)	Eosinophilia, asthma, sinusitis (60-80%), skin lesions (50-70%)	Mononeuritis multiplex	20%
Granulomatosis with polyangiitis (Chapter 249)	c-ANCA (75-90%) p-ANCA (<20%)	Pulmonary and renal involvement	Mononeuritis multiplex	15%
Polyarteritis nodosa	Elevated ESR (85%), positive serology, hepatitis B (30%), ANCA (<10%)	Multiple organs (skin, joints, renal, gastrointestinal)	Mononeuritis multiplex	60%
Mixed cryoglobulinemia (Chapter 173)	Hepatitis C (80-90%), reduced complement (70-90%), RF (70-90%), elevated ESR (70%).	Skin (purpura, livedo), joints, Raynaud phenomenon	Mononeuritis multiplex	20-90%
Sjögren syndrome (Chapter 247)	α-Ro/SS-A (60%), α-La/SS-B (50%)	Dry eyes, dry mouth; 90% are women	Multiple patterns	25%
Nonsystemic peripheral nerve vasculitis	Elevated ESR (50%), positive ANA (25%), reduced complement (5%)	Muscle disease (25%)	Mononeuritis multiplex	100%

ANCA = antineutrophil cytoplasmic antibodies; α-Ro/SS-A = anti–Sjögren's-syndrome–related antigen A autoantibodies; c-ANCA = cytoplasmic antineutrophil cytoplasmic antibodies; ESR = erythrocyte sedimentation rate; La/SS-B = La/Sjögren syndrome antigen B; p-ANCA = perinuclear antineutrophil cytoplasmic antibodies; RF = rheumatoid factor.

motor neuropathy and multifocal acquired demyelinating sensory and motor neuropathy cause asymmetrical weakness, but neither causes pain; furthermore, multifocal motor neuropathy does not cause sensory loss. Asymmetrical isolated sensory loss occurs in some forms of sensory neuronopathy that are caused by dorsal root ganglionopathy.

TREATMENT

Treatment for vasculitic neuropathy should be based on the specific form and clinical situation. Patients with large arteriole systemic vasculitis are at risk for rapid progression and disability, so treatment should be more aggressive, for example, oral prednisone (1 mg/kg) or intravenous methylprednisolone (1000 mg/day for 3 to 5 days) as induction therapy. Oral prednisone is continued at this dose for 1 to 2 months before instituting a slow taper. Maintenance cyclophosphamide (1 g/m^2 IV monthly for 6 months, or 2 mg/kg orally daily) is usually required for 3 to 6 months. If ongoing therapy is needed, cyclophosphamide may be replaced with oral methotrexate (e.g., starting at 7.5 to 15 mg/week) or azathioprine (e.g., starting at 2 to 3 mg/kg/day), with the dose ultimately decreased if the treatments prove effective. Patients with refractory vasculitis may benefit from rituximab (usually at a dose of 325 mg/m^2 weekly for four doses), IVIG (typically 1 g/kg every 3 to 4 weeks), or plasma exchange.

Because patients with nonsystemic vasculitic neuropathy usually have a more benign course than do patients with systemic vasculitis, alternate-day oral prednisone (e.g., 60 to 80 mg every other day) is often adequate therapy. Azathioprine or weekly methotrexate can be used as a glucocorticoid-sparing agent.

Patients with viral-induced peripheral nerve vasculitis, such as hepatitis C–associated cryoglobulinemia, require treatment of the underlying viral illness. Clinically significant vasculitic neuropathy can be treated as previously outlined.

PROGNOSIS

Most systemic and nonsystemic vasculitis cases respond at least partially to treatment. For systemic vasculitic neuropathy, the prognosis is linked to that of the causative disease, whereas isolated peripheral nervous system vasculitis has a better prognosis.

NEUROPATHIES ASSOCIATED WITH MONOCLONAL GAMMOPATHIES AND MULTIPLE MYELOMA

Monoclonal gammopathy and multiple myeloma (Chapter 173) are associated with multiple patterns of neuropathy, including a distal symmetrical polyneuropathy; polyneuropathy, organomegaly, endocrinopathy, myeloma protein, and skin changes (POEMS) syndrome; light chain amyloidosis; and distal acquired demyelinating syndrome, which is a variant of chronic inflammatory demyelinating polyradiculoneuropathy characterized by antibodies to myelin-associated glycoprotein in 50% of patients.[19] Multifocal motor neuropathy may occur with IgM gammopathies with specificity for GM_1 ganglioside (reviewed earlier). Patients with typical chronic inflammatory demyelinating polyradiculoneuropathy have a monoclonal gammopathy in the absence of the specific syndromes reviewed later; however, treatment and the response to it are similar to patients without gammopathy.

MONOCLONAL GAMMOPATHY OF UNCERTAIN SIGNIFICANCE

Monoclonal gammopathy refers to the presence in the β-γ region of serum protein electrophoresis of an abnormal spike (variably termed a paraprotein, monoclonal protein, or M protein) consisting of immunoglobulins of the same isotype, all produced by a single clone of abnormally proliferating lymphocyte/plasma cells. In some cases, the M protein is part of a malignant lymphoproliferative disease such as multiple myeloma, solitary plasmacytoma (IgG and IgA), Waldenström IgM macroglobulinemia (Chapter 173), chronic lymphocytic leukemia (Chapter 169), primary light-chain amyloidosis (Chapter 174), or cryoglobulinemia (Chapter 173). In most instances, however, monoclonal gammopathy is not initially associated with any of these disorders and is classified as a monoclonal gammopathy of uncertain significance (MGUS; Chapter 173),[20] although patients with MGUS have a 1 to 2% per year risk of progressing to myeloma or another hematologic disease.

EPIDEMIOLOGY

Monoclonal gammopathy is seen in 5 to 8% of patients with peripheral neuropathy of unknown etiology. However, MGUS is frequent, being found in 1% of the population older than 50 years and in 3% older than 70 years, and most subjects with MGUS do not have neuropathy. In some cases, the co-occurrence of neuropathy and M protein may be a coincidence.

The prevalence of neuropathy is higher in patients with IgM versus IgG or IgA M proteins. The prevalence of symptomatic neuropathy associated with IgM monoclonal gammopathy in patients older than 50 years is approximately 20 per 100,000. In half of such patients, the M protein reacts with either the HNK1 carbohydrate moiety of MAG or with other glycoproteins (MPZ, PMP22) and glycolipids (sulfoglucuronylparagloboside [SGPG] and lactosaminylparagloboside [SGLPG]). IgM M proteins associated with neuropathy may also bind to other neural antigens.

In patients with IgG monoclonal gammopathy and neuropathy, the relationship is less clear than with IgM. Although about 10% of patients with multiple myeloma have neuropathy, in most cases, the M protein does not react with a neural antigen, and the neuropathy does not improve with therapy (see later).

PATHOBIOLOGY

The underlying pathobiology of neuropathy associated with MGUS and multiple myeloma is unknown.

CLINICAL MANIFESTATIONS

Patients with MGUS typically present with a slowly progressive distal symmetrical peripheral polyneuropathy that is clinically indistinguishable from cryptogenic sensory peripheral neuropathy. Patients with multiple myeloma also typically have a slowly progressive sensory greater than motor peripheral polyneuropathy, although motor-predominant forms have been described.

DIAGNOSIS

Diagnosis is based on demonstration of a monoclonal gammopathy on serum protein electrophoresis or immunoelectrophoresis. Immunoelectrophoresis has a higher sensitivity than serum protein electrophoresis, but serum protein electrophoresis is required to define the heavy- and light-chain of MGUS. Patients with a non-IgG gammopathy, anemia, constitutional symptoms, or a high weight gammopathy (>15 g/L) require a full hematologic evaluation (Chapter 173). Patients with a distal symmetrical sensory polyneuropathy, a low level of monoclonal IgG or IgM, and normal hematologic values can be followed with yearly paraprotein measurements. The presence of distal weakness, tremor, severe pain, autonomic dysfunction, or rapid progression should prompt a more extensive evaluation for another cause for neuropathy, either related to the monoclonal gammopathy (e.g., POEMS, see later) or as a distinct disorder.

TREATMENT

Treatment of MGUS neuropathy is largely symptomatic, because treatment of the underlying monoclonal gammopathy does not improve the neuropathy. In contrast, treatment of multiple myeloma may improve the neuropathy.

PROGNOSIS

In patients whose myeloma responds to treatment, more than 50% have improvement in neuropathy. Patients with MGUS usually have a disease course similar to cryptogenic sensory peripheral neuropathy, with slow progression and minimal disability.

POEMS SYNDROME

The component features of POEMS syndrome are *P*olyneuropathy, *O*rganomegaly, *E*ndocrinopathy, *M*yeloma protein, and *S*kin changes. POEMS syndrome is a rare paraneoplastic neuropathy associated with osteosclerotic myeloma or Castleman disease (Chapters 171 and 359).[21]

EPIDEMIOLOGY

Approximately 50% of patients with the osteosclerotic form of myeloma have neuropathy.

PATHOBIOLOGY

The underlying mechanism of neuropathy in POEMS syndrome is unknown, although the very frequent elevation of vasoactive growth factors such as vascular endothelial growth factor (VEGF), the levels of which correlate with disease severity, suggest vascular permeability as a contributing mechanism.

CLINICAL MANIFESTATIONS

Neuropathy typically presents with distal numbness and pain progressing to weakness that is often in the pattern of a length-dependent polyneuropathy. The progressive nature and severity of weakness often suggest chronic inflammatory demyelinating polyradiculoneuropathy, although proximal weakness is less common in POEMS. The general physical examination should evaluate possible organomegaly (hepatomegaly, splenomegaly, or lymphadenopathy), features of volume overload (edema, ascites, or pleural effusions), endocrinopathy (diabetes, hypothyroidism, gynecomastia, amenorrhea, and hypogonadism), and skin changes.

DIAGNOSIS

The monoclonal protein usually has a lambda light chain, and any patient with a progressive neuropathy or suspected chronic inflammatory demyelinating polyradiculoneuropathy with a lambda monoclonal gammopathy should be carefully examined and evaluated for POEMS syndrome, as should patients who are thought to have chronic inflammatory demyelinating polyradiculoneuropathy but fail to respond to immunotherapy. Important diagnostic clues include common skin changes such as hyperpigmentation or hypertrichosis, edema, gynecomastia, and papilledema (Fig. 388-5). However, most patients do not manifest the full syndromic spectrum of POEMS (Table 388-6).

Nerve conduction studies often demonstrate some features of demyelination, although axon loss is common. Blood levels of VEGF are elevated to greater than 200 pg/mL in many patients (sensitivity of 68% and specificity of 95%), and the concentration increases as the disease progresses.

TREATMENT

Treatment of POEMS syndrome is based on directing therapy at the clonal plasma cell expansion. Modalities include radiation of osteosclerotic lesions, systemic chemotherapy (Chapter 173), and autologous stem cell transplantation. Treatments typically recommended for chronic inflammatory demyelinating polyradiculoneuropathy are usually ineffective.

LIGHT CHAIN AMYLOIDOSIS

Light chain amyloidosis (Chapter 174), which shares many features with hereditary forms of amyloidosis, affects peripheral nerve in about 20% of patients. The heart and kidney are commonly affected.

FIGURE 388-5. Optic disc edema in a patient with polyneuropathy, organomegaly, endocrinopathy, myeloma protein, skin change (POEMS) syndrome.

TABLE 388-6 DIAGNOSTIC CRITERIA FOR POLYNEUROPATHY, ORGANOMEGALY, ENDOCRINOPATHY, MYELOMA PROTEIN, SKIN CHANGE (POEMS) SYNDROME

Mandatory major criteria (both must be present)	Polyneuropathy Monoclonal plasma cell-proliferative disorder (almost always lambda)
Other major criteria (1 required)	Castleman disease Sclerotic bone lesions Elevated vascular endothelial growth factor
Minor criteria (1 required)	Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy) Extravascular volume overload (edema, pleural effusion, ascites) Endocrinopathy (diabetes, hypothyroidism, gynecomastia, amenorrhea, and hypogonadism) Skin changes (hyperpigmentation, hypertrichosis) Papilledema Thrombocytosis or polycythemia

EPIDEMIOLOGY

Light-chain amyloidosis is more common in men (2 : 1 ratio) and has a median age at onset in the seventh decade.

PATHOBIOLOGY

Monoclonal light chains, either lambda or kappa, misfold and aggregate into beta-pleated sheets, which deposit in susceptible tissues. The most commonly involved tissues are kidneys, liver, heart, the carpal tunnel, and the peripheral nervous system.

CLINICAL MANIFESTATIONS

Patients typically present with a relentlessly progressive, distal, symmetrical polyneuropathy that is usually painful and associated with autonomic dysfunction, often with fatigue and unexplained weight loss. Orthostatic hypotension is common, and men often note erectile dysfunction. A minority of patients have a painless neuropathy or do not have prominent autonomic symptoms (Chapter 386). Other organ systems are usually involved, most often leading to renal failure and heart failure.

DIAGNOSIS

Most patients with light chain amyloidosis have free light chains in the urine. Confirmation requires tissue diagnosis, usually with bone marrow biopsy and fat pad biopsy or aspiration (Chapter 174). Biopsy of other affected tissues may be necessary.

TREATMENT

Treatment (Chapter 174) consists of systemic chemotherapy and, for patients who are candidates, stem cell transplantation. When successful, treatment may result in stabilization of the neuropathy.

DISTAL ACQUIRED DEMYELINATING SYMMETRIC SYNDROME

Distal acquired demyelinating symmetric syndrome, which is an uncommon variant seen in only about 7% of patients with chronic inflammatory demyelinating polyradiculoneuropathy, preferentially affects the distal nerve segments, where it results in distal weakness and numbness, often with tremor.[22]

PATHOBIOLOGY

Approximately 50% of patients have an IgM monoclonal protein that immunoreacts with myelin associated glycoprotein (MAG). Nerve biopsy demonstrates segmental demyelination, with deposits of M protein and complement in patients with anti-MAG related distal acquired demyelinating symmetric syndrome. The myelin lamellae are often widened on sural nerve biopsies, but a biopsy is not necessary for diagnosis. High titers (>1 : 10,000) of anti-MAG IgM antibodies are associated with neuropathy, and intraneural or systemic injection of anti-MAG IgM M proteins causes complement-mediated demyelination of nerves in animals.

CLINICAL MANIFESTATIONS

Most patients are initially seen in their sixth to seventh decade of life with dysesthesias and paresthesias in their legs and unsteadiness while walking because of loss of proprioception. Distal weakness subsequently ensues, and many patients develop a coarse postural and action tremor. Disability and reduced quality of life are determined by weakness, tremor, ataxia, and fatigue. Physical examination shows a length-dependent large fiber sensory neuropathy.

DIAGNOSIS

Nerve conduction studies demonstrate evidence of distal demyelination with markedly prolonged motor distal latencies. The presence of an IgM monoclonal gammopathy with high titer anti-MAG antibodies is observed in 50% of patients.

TREATMENT

Patients with anti-MAG neuropathy and distal acquired demyelinating syndrome do not respond as well to immunotherapy as do patients with typical chronic inflammatory demyelinating polyradiculoneuropathy. One small trial of rituximab failed to show substantial improvement although case series data suggest up to 30% of patients may have benefit, particularly patients with high antibody titers. Multiple other agents have been tried without success.

PARANEOPLASTIC NEUROPATHIES

DEFINITION

Paraneoplastic neuropathies (Chapter 164) are a remote effect of cancer not caused by metastatic invasion of neural tissue; radiation therapy or chemotherapy; metabolic, vascular, or hormonal disturbances; or opportunistic infections.[23] Neural injury is the result of the host immune responses to a tumor antigen or antigens that are also present in neural tissues. Paraneoplastic peripheral neuropathy is also termed a sensory neuronopathy or ganglionopathy.

EPIDEMIOLOGY

Paraneoplastic syndromes occur in less than 1% of patients with cancer; peripheral neuropathy is only one of the paraneoplastic syndromes. Although more than 25% of patients with cancer have evident neuropathy on neurologic examination, the relationship to malignancy is unclear in most. Paraneoplastic neuropathy may develop before, during, or after the tumor is diagnosed. Certain patterns of neuropathy, such as a non–length dependent sensory neuronopathy (dorsal root ganglionopathy), suggest a paraneoplastic etiology and should prompt a thorough investigation for an underlying cancer. Small cell carcinoma of the lung is by far the most common underlying neoplasm, followed by carcinoma of the stomach, breast, colon, rectum, ovary, and prostate. A similar neuronopathy/ganglionopathy can be seen in Sjögren syndrome (Chapter 247), rarely with HIV infection, as a complication of platin chemotherapy or checkpoint inhibitor therapy, and with pyridoxine toxicity.[24]

PATHOBIOLOGY

Subacute sensory neuronopathy, the most characteristic paraneoplastic neuropathy, results from an immune-mediated ganglionitis that destroys sensory neurons in the dorsal root ganglia. Mononuclear inflammatory infiltrates composed of CD4+ and prominent CD8+ T cells, along with plasma cells, are found in the stroma surrounding the dorsal root ganglion neurons. Other findings include atrophy of the dorsal roots; loss of sensory neurons, which appear to be replaced by a proliferation of satellite cells (Nageotte nodule); axonal degeneration; and secondary degeneration of the dorsal column of the spinal cord. Inflammatory infiltrates can also be found in peripheral nerves or muscle. Sural nerve biopsies typically reveal only loss of myelinated nerve fibers and are not useful for diagnosis.

CLINICAL MANIFESTATIONS

Subacute sensory neuronopathy is characterized by subacute, progressive impairment of all sensory modalities and is associated with severe sensory ataxia and areflexia. Subacute sensory neuropathy may precede the diagnosis of tumor by months or even years. At onset, patients may have shooting pain and burning sensations. Other symptoms include numbness, tingling, and a progressive sensory loss that may be asymmetrical. Symptoms usually progress rapidly to involve all four limbs, the trunk, and face. Findings may then stabilize, although by this time the patient is often totally disabled. Occasional patients have an indolent course.

Neurologic examination reveals loss of deep tendon reflexes and involvement of all modalities of sensation; large fiber modalities such as vibration and joint position sense are most severely affected. The loss of position sense may lead to severe sensory ataxia with pseudoathetoid movements of the hands and an inability to walk despite normal strength. Cranial nerve involvement includes sensorineural deafness, loss of taste, and facial numbness. The asymmetrical pattern of symptoms sometimes suggests a radiculopathy or plexopathy.

A paraneoplastic encephalomyelitis characterized by patchy, multifocal neuronal loss in regions of the cerebral hemispheres, the limbic system, the cerebellum, the brain stem, the spinal cord, and autonomic ganglia often develops in patients with subacute sensory neuropathy. Autonomic symptoms include impotence, dry mouth, and constipation.

DIAGNOSIS

The diagnosis is based on recognizing the typical neuropathy in the setting of malignancy. The results of routine laboratory studies are generally normal. The diagnosis is supported by finding serum polyclonal IgG anti-Hu antibodies, also called antineuronal antibodies type 1, or by indirect immunofluorescence or immunohistochemistry and confirmed by Western blot analysis.

Subacute painful, asymmetrical neuropathy or neuronopathy in an elderly patient should prompt a search for carcinoma of the lung because small cell lung cancer accounts for more than 80% of the associated tumors. Subacute sensory neuropathy also has been reported in patients with adenocarcinoma of the lung, breast, ovary, stomach, colon, rectum, and prostate, as well as

Hodgkin and non-Hodgkin lymphoma. In patients with no evidence of cancer, detection of anti-Hu antibodies should prompt a computed tomography study of the chest with special attention to the mediastinal lymph nodes. The use of whole-body positron emission tomography with fluorodeoxyglucose has been advocated for early diagnosis in patients with anti-Hu antibodies or clinical suspicion of subacute sensory neuropathy because it may reveal neoplastic adenopathy months before computed tomography or magnetic resonance imaging.

TREATMENT

Subacute sensory neuropathy responds poorly to plasma exchange, IVIG, or immunosuppressant medications, even when such treatment is started early in the course of the disease. Successful treatment of the tumor rarely induces remission of subacute sensory neuropathy, but it may stabilize symptoms.

THE DIABETIC NEUROPATHIES

Diabetes causes a broad spectrum of neuropathies that can be divided into chronic (distal symmetrical polyneuropathy and autonomic neuropathy) and acute forms (diabetic amyotrophy, acute cranial mononeuropathies and truncal radiculopathy, and treatment-induced neuropathy of diabetes).[25] Patients with prediabetes, obesity, and the metabolic syndrome are at risk for cryptogenic sensory peripheral neuropathy.

EPIDEMIOLOGY

Diabetes (Chapter 210) is the most common cause of neuropathy in the world. Distal symmetrical polyneuropathy, which occurs in about 50% of patients, is one of the most costly and disabling diabetic complications. Autonomic neuropathy is also common (erectile dysfunction develops in 20 to 60% of diabetic men), but widespread autonomic dysfunction (Chapter 386) develops in less than 5% of patients.

DISTAL SYMMETRICAL AND AUTONOMIC POLYNEUROPATHY

PATHOBIOLOGY

The pathogenesis of diabetic distal symmetrical and autonomic polyneuropathy involves both microvascular and metabolic abnormalities. In type 1 diabetes, increased blood glucose levels are clearly linked to the risk of neuropathy. In type 2 diabetes, other metabolic features, including hyperlipidemia and obesity, are important contributors to the risk of neuropathy. Specific pathogenic mechanisms, ultimately leading to mitochondrial injury and axon loss in both types of diabetes, include activation of the polyol pathway, formation of advanced glycation end products, altered diacylglycerol/protein kinase activity, and oxidative stress.

CLINICAL MANIFESTATIONS

Distal symmetrical polyneuropathy can be symptomatic or asymptomatic. Patients with symptoms develop numbness, tingling, and, in 20% of cases, neuropathic pain in the feet that over time progresses proximally toward the knees. In type 2 diabetes, small-diameter axons responsible for pain sensation are injured first. With time, injury to large-diameter fibers results in loss of proprioception and touch sensation, leading to gait instability and risk of ulceration and amputation. Patients with asymptomatic neuropathy often present later in the disease with large-fiber neuropathy and severely reduced sensation in the feet. Weakness is minimal, even in the distal foot muscles. Once numbness reaches the knees, the fingers and hands may become involved. Ankle reflexes are generally absent, although patellar reflexes may be present.

Autonomic neuropathy (Chapter 386) typically presents after years of diabetes with gastroparesis (Chapters 122 and 210), constipation that may alternate with diarrhea, orthostatic hypotension, anhidrosis, cardiac arrhythmias, and erectile dysfunction. Autonomic abnormalities, which can be the most disabling component of diabetic neuropathy, pose a significant risk of cardiac mortality.

DIAGNOSIS

Diagnosis is based on a combination of symptoms and signs of polyneuropathy. Distal symmetrical polyneuropathy may be the first symptom of diabetes, with the diagnosis apparent only after careful evaluation. Nerve conduction studies or skin biopsy can confirm the diagnosis if there is diagnostic uncertainty but are not routinely recommended.[26]

TREATMENT

Aggressive glycemic control reduces the risk of neuropathy in type 1 diabetes but not in type 2 diabetes, in which control of other metabolic risk factors may be equally important.[27] Several studies suggest diet and exercise may reduce neuropathic symptoms, including pain, and slow their progression. Gabapentin (up to 3600 mg/day in divided doses 3 to 4 times per day), pregabalin (150 to 300 mg/day in two or three divided doses), duloxetine (60 to 120 mg/day), and tricyclic antidepressants (e.g., amitriptyline, desipramine, or nortriptyline at doses of 25 to 100 mg daily) may be partially effective for treatment of neuropathic pain.[28,A9] Patients with loss of touch and protective sensation are at risk for foot ulceration and amputation.

DIABETIC LUMBOSACRAL RADICULOPLEXUS NEUROPATHY

Diabetic lumbosacral radiculoplexus neuropathy, commonly referred to as "diabetic amyotrophy," develops acutely or subacutely, most commonly in type 2 diabetes, with asymmetrical proximal leg pain that is typically severe. Atrophy and weakness of proximal thigh muscles ensues, and symptoms often spread to the contralateral side. Distal leg weakness is common, and some patients develop hand weakness. Diagnosis is based on clinical features. Nerve conduction studies and electromyography demonstrate an axonal polyradiculoneuropathy with frequent denervation in paraspinal muscles. CSF examination reveals an elevated protein with normal cell counts. Although not necessary for diagnosis, cutaneous sensory nerve biopsy demonstrates a small vessel vasculitis, thereby suggesting an autoimmune etiology. Half of patients require opiate analgesia and a wheelchair to assist with ambulation. Spontaneous recovery is typical, although up to 50% of patients do not regain baseline function. It is unclear if immunosuppressant therapy can alter the natural history, although a brief course of corticosteroids (e.g., 1 g solumedrol 3 times weekly with a tapering dose over 12 weeks) may improve pain.

TREATMENT-INDUCED NEUROPATHY OF DIABETES

Treatment-induced neuropathy of diabetes develops after rapid correction of severe hyperglycemia. Patients present with a subacute painful neuropathy with autonomic features. The distribution and severity of symptoms are proportional to the magnitude of rapid decline in the hemoglobin A_{1c} level. Patients whose hemoglobin A_{1c} drops by 2 to 3% over 3 months have a 20% risk of a distal predominant painful neuropathy, and patients with a drop of 4% or more have an 80% risk, often with more proximal involvement and severe pain. Treatment-induced neuropathy of diabetes is often associated with worsening diabetic retinopathy, suggesting a common microvascular mechanism, although the time course is also consistent with an inflammatory etiology. Neuropathy improves gradually, although most patients require symptomatic pain management.[29]

ACUTE FOCAL NEUROPATHIES

Truncal radiculopathy is characterized by the subacute onset of focal pain and sensory loss over a region of the trunk, with some patients developing segmental abdominal weakness appreciable as a bulge. Symptoms are similar to those of post-herpetic neuralgia. As with diabetic lumbosacral radiculoplexus neuropathy, many patients require aggressive pain management, and at least partial improvement occurs after a period of months.

Cranial neuropathies classically manifest as an acute oculomotor nerve palsy in which retro-orbital pain is followed by diplopia and ptosis. Pupillary fibers are often spared, thereby distinguishing the disorder from lesions that compress the oculomotor nerve and cause a dilated pupil. Similar findings may occur with the trochlear or abducens nerves. Bell palsy is more frequent in diabetic patients and is less likely to involve taste than in patients without diabetes.

INFECTIOUS NEUROPATHIES

NEUROPATHIES ASSOCIATED WITH HIV INFECTION

The peripheral nervous system may be involved in all phases of HIV infection (Chapters 355 and 359). The most common peripheral neuropathy is a distal, painful, sensory axonal polyneuropathy that is similar to the toxic neuropathy caused by nucleoside reverse transcriptase inhibitors (NRTIs), including zidovudine, zalcitabine, didanosine, stavudine, and lamivudine. When an iatrogenic neuropathy is suspected, discontinuation of NRTIs may improve symptoms. A neuropathy caused by HIV is likely to stabilize or improve with antiretroviral treatment.

Inflammatory neuropathies such as chronic or acute inflammatory demyelinating polyradiculoneuropathy can also occur in the early stages of HIV infection at the time of seroconversion; the CSF cytoalbumin dissociation usually seen with these conditions may not be evident in these patients because of a mild CSF mononuclear pleocytosis. The response of these neuropathies to plasma exchange or IVIG is generally good. In later stages of HIV infection, cytomegalovirus (Chapter 347) may cause either an acute lumbosacral polyradiculopathy as a result of direct invasion of nerve roots or a mononeuritis multiplex through a vasculitic mechanism.

NEUROPATHIES ASSOCIATED WITH HERPES ZOSTER

Varicella-zoster virus (Chapter 346) usually remains latent in cranial or spinal ganglia after resolution of a systemic infection. Reactivation, which is more frequent in elderly and immunocompromised patients, causes a vesicular skin eruption accompanied by pruritus and dysesthesias. Herpes zoster resolves spontaneously but is frequently followed by post-herpetic neuralgia, which is characterized by severe pain persisting for more than 6 weeks after the rash appears. Early treatment with oral acyclovir (800 mg, five times daily for 7 days) may reduce both the duration of the acute phase and the risk for post-herpetic neuralgia. The use of concomitant corticosteroids in addition to acyclovir improves acute pain without exacerbating viral spread but does not reduce the incidence or severity of post-herpetic neuralgia. Vaccination with the herpes zoster subunit vaccine reduces the risk of post-herpetic neuralgia (Chapter 346).

NEUROPATHY ASSOCIATED WITH LYME DISEASE

Borrelia burgdorferi (Chapter 296) causes a disease with three stages. In the first stage, shortly after and in the same area of a tick bite, a nonpruritic rash (erythema migrans) appears and spontaneously disappears after a few weeks. The second stage is frequently associated with neurologic complications such as lymphocytic meningitis and focal and multifocal peripheral and cranial neuropathies; characteristic manifestations are unilateral or bilateral facial palsy and radiculitis. The third stage is associated with severe neurologic complications, including encephalopathy, encephalomyelitis, and a predominantly sensory axonal polyneuropathy. A lymphocytic pleocytosis in CSF and demonstration of *B. burgdorferi* infection in serum or CSF are the main laboratory findings. Treatment is discussed in Chapter 296.

NEUROPATHY ASSOCIATED WITH LEPROSY

Leprosy (Chapter 301) is infrequent in the United States but is a common cause of peripheral neuropathy in some developing countries. Leprosy presents in different forms, depending on the host's immune system. Patients with normal cell-mediated immunity are more likely to have a tuberculoid form characterized by hypopigmented skin lesions associated with decreased sensation. In patients with abnormal cell-mediated immunity, the more severe lepromatous form with large disfiguring lesions may develop. A mononeuritis multiplex pattern with prominent superficial sensory loss is the most typical clinical manifestation of leprosy. If treated early, neuropathies in leprosy improve. World Health Organization recommendations call for combination therapy that includes dapsone (50 to 100 mg/day or 200 to 250 mg/week), rifampicin (600 mg monthly), and clofazimine (100 mg/day).

NEUROPATHY ASSOCIATED WITH DIPHTHERIA

Vaccination has made diphtheria (Chapter 272) rare in developed countries, but it is an important cause of subacute neuropathy in developing countries. Some strains of *Corynebacterium diphtheriae* produce a potent neurotoxin that causes palatal weakness, lens accommodation deficits, and extraocular palsies. These acute manifestations are followed by limb paralysis that resembles acute inflammatory demyelinating polyradiculoneuropathy (see earlier). The neuropathy caused by the neurotoxin usually resolves with resolution of the infection. The diphtheria organism can be eradicated by therapy with antibiotics such as erythromycin (2 g/day intravenously divided twice daily for adults) or penicillin (procaine penicillin G, 1.2 million U/day intramuscularly divided twice daily for 14 days). However, the neuropathy, as with other manifestations of the disease, generally requires treatment with diphtheria antitoxin, a hyperimmune antiserum produced in horses. Depending on the severity of the disease, antitoxin is administered intramuscularly or intravenously (80,000 to 120,000 units for extensive disease for 3 or more days; Chapter 272).

TOXIC AND DEFICIENCY SYNDROMES

In Western countries, toxic neuropathies are frequently the side effects of a medication[30] rather than a result of environmental exposure (see Table 388-2). In most cases, iatrogenic neuropathy is manifested as a length-dependent or "dying-back" axonal neuropathy. Treatment requires a correct diagnosis and discontinuation of the drug. The most common category of drugs associated with neuropathy are antineoplastic agents (especially paclitaxel and oxaliplatin). In some cases, the neuropathy progresses for weeks following discontinuation of exposure (hexane and cisplatin), a phenomenon referred to as "coasting," and improvement often requires many months.

Treatment is symptomatic. Duloxetine (30 mg orally once daily for 1 week, then 60 mg daily for 4 weeks) improves pain in chemotherapy-induced peripheral neuropathy.[A10]

Peripheral polyneuropathy may also develop with deficiency of a number of vitamins and nutrients (Chapter 199).[31] Deficiency of vitamin B_{12} results in severe combined degeneration of the spinal cord and peripheral nerves, accompanied by tingling feet and a sensory ataxia. Copper deficiency (Chapter 199), often due to zinc overload, causes a similar syndrome. Vitamin E deficiency causes ataxia and a phenotype similar to Friedreich ataxia (Chapter 379). Vitamin B_1 (thiamine) deficiency may cause a severe sensorimotor axonal neuropathy in addition to the classic triad of Wernicke encephalopathy (ataxia, ophthalmoparesis, and encephalopathy; Chapter 384). Vitamin B_6 (pyridoxine) is unique in that neuropathy may develop with either deficiency or overload. Excessive doses of B_6 result in a sensory neuronopathy (ganglionopathy) that ranges in severity from mild distal numbness and tingling with modest exposure to severe sensory ataxia with higher doses.

An acute axonal sensorimotor peripheral polyneuropathy with ataxia and areflexia in the setting of nutritional deficiency has been described in alcoholic patients and in patients who fail to follow the recommended nutritional supplementation plan following bariatric surgery. Some patients develop significant weakness. Serum thiamine and vitamin B_6 levels are often reduced,[32] and most patients respond to nutritional repletion.

CRITICAL ILLNESS NEUROPATHY

Critical illness polyneuropathy is an acute or subacute axonal length–dependent axonal neuropathy that occurs in critically ill patients with sepsis. It is often associated with critical illness myopathy (Chapter 389), which has resulted in some confusion regarding the extent to which clinical symptoms are attributable to the neuropathy or the myopathy. Up to 70% of critically ill patients with sepsis (Chapter 94) develop some degree of critical illness neuropathy, and patients with the systemic inflammatory response syndrome are at particular risk. Treatment is directed at the underlying systemic disorder that led to critical illness and sepsis. Most patients experience at least some degree of recovery, with the ultimate disability determined by the degree of persistent weakness.

NEURALGIC AMYOTROPHY (IDIOPATHIC BRACHIAL PLEXITIS)

Neuralgic amyotrophy, also known as idiopathic brachial plexitis, typically presents with acute severe shoulder and proximal arm pain followed by rapidly progressive arm weakness and atrophy within several days. Hereditary neuralgic amyotrophy is due to autosomal dominant mutations in the *SEPT9* gene, which encodes the Septin 9 protein. Idiopathic neuralgic amyotrophy is thought to be inflammatory because 50% of patients describe a preceding infection.

Initially thought to be very uncommon, recent data suggest the incidence may be as high as 1 : 1000. Although 70% of patients have a typical presentation, the remainder present with other focal variants, including involvement of individual upper extremity peripheral nerves, including the phrenic and laryngeal nerves. Recurrent episodes occur in 25% of idiopathic cases. Treatment is focused on management of neuropathic pain (Chapter 26).

COMPRESSIVE MONONEUROPATHIES

Peripheral nerves are vulnerable to compression at specific anatomic sites. The most common are median nerve compression at the wrist within the carpal tunnel (carpal tunnel syndrome), ulnar nerve compression at the elbow (cubital tunnel syndrome), and peroneal nerve compression over the lateral fibular head.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome, which is caused by compression of the median nerve at the wrist, is the most common compressive mononeuropathy.[33] The carpal tunnel is bounded by the carpal bones and carpal ligament, and it is traversed by the median nerve and flexor tendons. Risk factors include repetitive motion of the wrist and fingers, as well as structural abnormalities within the tunnel such as osteoarthritis, synovial cysts, myxedema, and (rarely) amyloid deposition. Carpal tunnel syndrome is also common during pregnancy, but it usually resolves following delivery.

Symptoms typically include paresthesias of the first three fingers, often at night, and are relieved by shaking or elevating the hand. Patients also commonly

FIGURE 388-6. Bell palsy is characterized by a lower motor neuron pattern of weakness. At rest, there is slight widening of the right palpebral fissure (**A**). With smiling, there is deviation of the corner of the mouth towards the normal side on the left (**B**). There is weakness of eye closure on the right while closing the eyes (**C**). When the patient is asked to look surprised, there is weakness (or flattening) of the frontalis muscles on the right (**D**). Upper motor neuron facial weakness, such as is seen with a stroke, would not cause forehead weakness.

experience subjective numbness in a broader distribution including the medial hand (ulnar distribution) and as proximal as the shoulder. In severe cases, patients have objective sensory loss in the median nerve distribution as well as atrophy and weakness of median-innervated thenar muscles (abduction and opposition). Provocative maneuvers such as the *Tinel* (tapping the carpal tunnel) and *Phalen* (sustained flexion of the wrist) signs have poor diagnostic utility compared with nerve conduction studies. Neutral splinting of the wrist during sleep is effective for most patients. Subacute painful, asymmetrical neuropathy or neuronopathy in an elderly patient should prompt a search for carcinoma of the lung because small cell lung cancer (Chapter 177) accounts for more than 80% of the associated tumors. Methylprednisolone injections can provide temporary relief,[A11] as can injection of 5% dextrose,[A12] but patients who fail to respond or whose symptoms recur usually obtain relief from endoscopic or open decompressive surgery, with the endoscopic approach generally preferred.[A13]

CUBITAL TUNNEL SYNDROME

Cubital tunnel syndrome is manifested by numbness and tingling of the fifth finger and the outer half of the fourth finger. The approach is as for carpal tunnel syndrome, except that exercises may be helpful. If symptoms warrant, treatment is by decompression surgery.[34]

BELL PALSY

Unilateral facial paralysis of acute onset frequently occurs on an idiopathic basis (Bell palsy). The diagnosis is one of exclusion. Facial nerve palsies also occur in the setting of *herpes zoster oticus* and are associated with otalgia and varicelliform lesions affecting the external ear, ear canal, or tympanic membrane. Facial paralysis of a lower motor neuron type can be caused by carcinomatous meningitis (Chapter 381), sarcoidosis (Chapter 83), Lyme disease (Chapter 296), and HIV infection (Chapters 355 and 359). Lower motor neuron facial weakness is characterized by weakness of the lower face and frontalis muscle (Fig. 388-6), whereas upper motor neuron weakness (such as is seen with a stroke) involves only the lower face.

Primary tumors of the facial nerve can cause rapidly developing facial paralysis. Facial paralysis can also occur in *CNS disease* affecting the pontomedullary junction, such as stroke or multiple sclerosis (Chapter 380).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most cases of facial paralysis are idiopathic. Patients typically notice facial paralysis on inspection in the mirror in the morning. Facial paralysis may be heralded or accompanied by pain behind the ear. The severity of paralysis varies widely.

TREATMENT

Ten days of oral corticosteroids (prednisolone 25 mg twice daily for 10 days) administered early in the course increases the return of facial function from 63 to 83% at 3 months in patients with idiopathic Bell palsy.[35] Acyclovir is of no independent benefit, but adding it (at a dose of 400 mg five times daily for 7 days, or twice this dose for varicella zoster) to corticosteroid therapy appears to improve outcomes in severe cases. In severe cases, protection of the cornea from drying and injury is essential.

PROGNOSIS

Most patients improve, but about 10% of patients have little recovery. Aberrant regeneration of the facial nerve can cause synkinesis, such as "jaw winking" (when the eye is closed) or tearing accompanying salivation (syndrome of crocodile tears).

TRIGEMINAL NEURALGIA (TIC DOULOUREUX)

Trigeminal neuralgia and other painful cranial neuralgias are discussed in Chapter 367.

389 MUSCLE DISEASES

DUYGU SELCEN

DEFINITION

Muscle diseases, which are also called myopathies, are disorders of skeletal muscle structure or function. Myopathies can be primary and occur in isolation, or they can be part of a multisystem disorder.

EPIDEMIOLOGY

Many muscle diseases (Table 389-1) are inherited as autosomal dominant, autosomal recessive, X-linked, or maternal (mitochondrial) conditions.[1] Environmental factors that may precipitate myopathies include recent infection, foreign travel, exposure to medications such as statins, and alcohol abuse (Chapter 364). Exercise commonly precipitates symptoms in patients with metabolic myopathies, whereas exposure to cold and high-carbohydrate or potassium-rich food can precipitate weakness in muscle channelopathies.

The prevalence of muscle disease is estimated to be about 1 per 1000 people, including acute and transient disorders (e.g., myositis owing to infectious or toxic causes) and chronic inflammatory or genetic disorders that cause substantial morbidity over decades or a lifetime. Myopathies can cause premature death owing to neuromuscular weakness and secondary respiratory infections or to involvement of other organs in multisystem diseases. Myocardial involvement, which is particularly common in some muscle diseases, can cause heart failure or life-threatening arrhythmias.

PATHOBIOLOGY

Muscle disease can result from a perturbation in the anatomy or any of the physiologic processes required for muscle contraction or the genes that control them. Skeletal muscle is part of a motor unit, which is defined as the anterior horn cell body, its axon, the neuromuscular junction, and the skeletal muscle fibers innervated by the one axon. The motor unit is coordinated in a manner that allows efficient muscle contraction and function. The number of muscle fibers innervated by each motor unit varies from a few (e.g., in muscles controlling very precise movements, such as extraocular muscles) to more than 1000 (e.g., large and powerful but less precise muscles, such as the quadriceps).

Skeletal muscle is composed of myriad muscle fibers. Muscle fibers, which are multinucleated cells formed by fusion of myoblasts during development, are surrounded by a plasma membrane, the sarcolemma, which is surrounded by a basal lamina and endomysial connective tissue. Groups of muscle fibers compose the fascicles, which are surrounded by perimysium, and the groups of fascicles in turn are surrounded by epimysium. Nerve branches, blood vessels, muscle spindles, and fat cells lie within the connective tissue of the muscle.

Each muscle fiber is composed of myofibrils, which themselves are composed of repeat units a few microns long called sarcomeres. The sarcomere consists of a highly organized protein network that gives the muscle fiber its characteristic striated appearance. Each sarcomere is flanked by two Z discs. Z discs are composed of multiple proteins, including α-actinin. Emanating from the Z disc are thin filaments, composed of actin, troponin, and tropomyosin. Thick filaments consist of myosin. Other structures comprise subcellular organelles, including the mitochondria, which are the principal energy source, the endoplasmic reticulum, and the transverse tubules that communicate with the extracellular space.

Muscle function (E-Fig. 389-1) is dependent on chemical energy from adenosine triphosphate (ATP). In the first 30 minutes of sustained activity, ATP is produced by the breakdown of glycogen (glycolysis), and after 30 minutes ATP is produced by fatty acid β-oxidation and oxidative phosphorylation within the mitochondria. The process that leads to muscle contraction begins with the generation of the muscle fiber action potential (Chapter 41), which initiates muscle contraction after it is propagated into the interior of muscle fiber through the transverse tubular system. The release of calcium from the endoplasmic reticulum triggers a coordinated series of events that lead to the coupling of excitation to contraction. Calcium binds to troponin, which interacts with tropomyosin and results in actin-myosin binding. The repeated formation and cleavage of actin-tropomyosin cross-bridges, in an ATP-dependent process, results in sliding of thick and thin filaments and shortening of the sarcomere.

The structural integrity of the muscle fiber surface membrane is maintained by a network of proteins within the muscle. Dystrophin is a key component of the subsarcolemmal cytoskeleton. In combination with several glycoproteins called sarcoglycans (α, β, δ, γ), dystroglycans (α, β), and syntrophins (α,β1, β2), which form the dystrophin-sarcoglycan complex, it anchors the contractile elements of the muscle fiber to the sarcolemma and to the extracellular basal lamina. The basal lamina contains several important proteins, such as collagen, fibronectin, and laminin, which includes merosin and related proteins. The intermediate filament proteins, including desmin, connect the Z disc and other organelles to the subsarcolemmal cytoskeleton.

CLINICAL MANIFESTATIONS

Muscle diseases often present with localized or diffuse muscle weakness, reduced exercise tolerance, resting or exercise-induced muscle pain, muscle enlargement or atrophy, cramps, delayed relaxation, or, rarely, myoglobinuria. These symptoms and signs can be masked by other neurologic or systemic features in patients with multisystem diseases.

History

The assessment of patients with neuromuscular diseases begins with a careful history, general physical examination, and detailed neurologic examination. The age of onset, the rate of progression, and whether the process is episodic, static, or progressive can provide important clues. Congenital and childhood-onset myopathies can be associated with reduced fetal movements, breech delivery, weak cry or suck, and the delayed acquisition of motor milestones. Weakness is the most common presenting symptom, but other symptoms of muscle disease include muscle pain, reduced exercise tolerance, change in the muscle bulk (hypertrophy or atrophy), abnormal spontaneous muscle activity, delayed relaxation, fatigue, or myoglobinuria. Weakness may be relatively static as in some congenital myopathies, progressive as in muscular dystrophies, intermittent as in periodic paralysis, fluctuating as in neuromuscular junction disorders (Chapter 390), or exercise related as in metabolic myopathies. The most common distribution of weakness is proximal or limb-girdle weakness, which results in difficulties in getting out of low chairs, a bathtub, or a car seat; climbing up and down stairs; arising from a squat; or getting off the floor. Proximal arm weakness manifests as difficulty reaching to shelves, washing or brushing hair, or raising arms to put on a shirt. Distal leg weakness can lead to difficulty walking on uneven surfaces, tripping over curbs, difficulty standing on the toes, or slapping feet owing to footdrop. Distal upper limb weakness results in difficulty opening jars, typing at a keyboard, writing, or buttoning clothes. Bilateral facial weakness can result in difficulty whistling, blowing up balloons, or drinking through a straw. Predominant involvement of ocular muscles can produce ptosis and diplopia. Weakness of the bulbar muscles manifests as difficulties with speech and swallowing, neck weakness that can lead to a dropped head, and respiratory muscle weakness that can lead to symptoms suggestive of nocturnal hypoventilation or respiratory failure. The early recognition of progressive respiratory failure is essential because it is treatable with noninvasive positive-pressure ventilation.

Fatigue and exercise intolerance can be presenting symptoms of muscle diseases, but they can also be multifactorial and nonspecific. In isolation, these symptoms usually do not indicate a primary muscle disease.

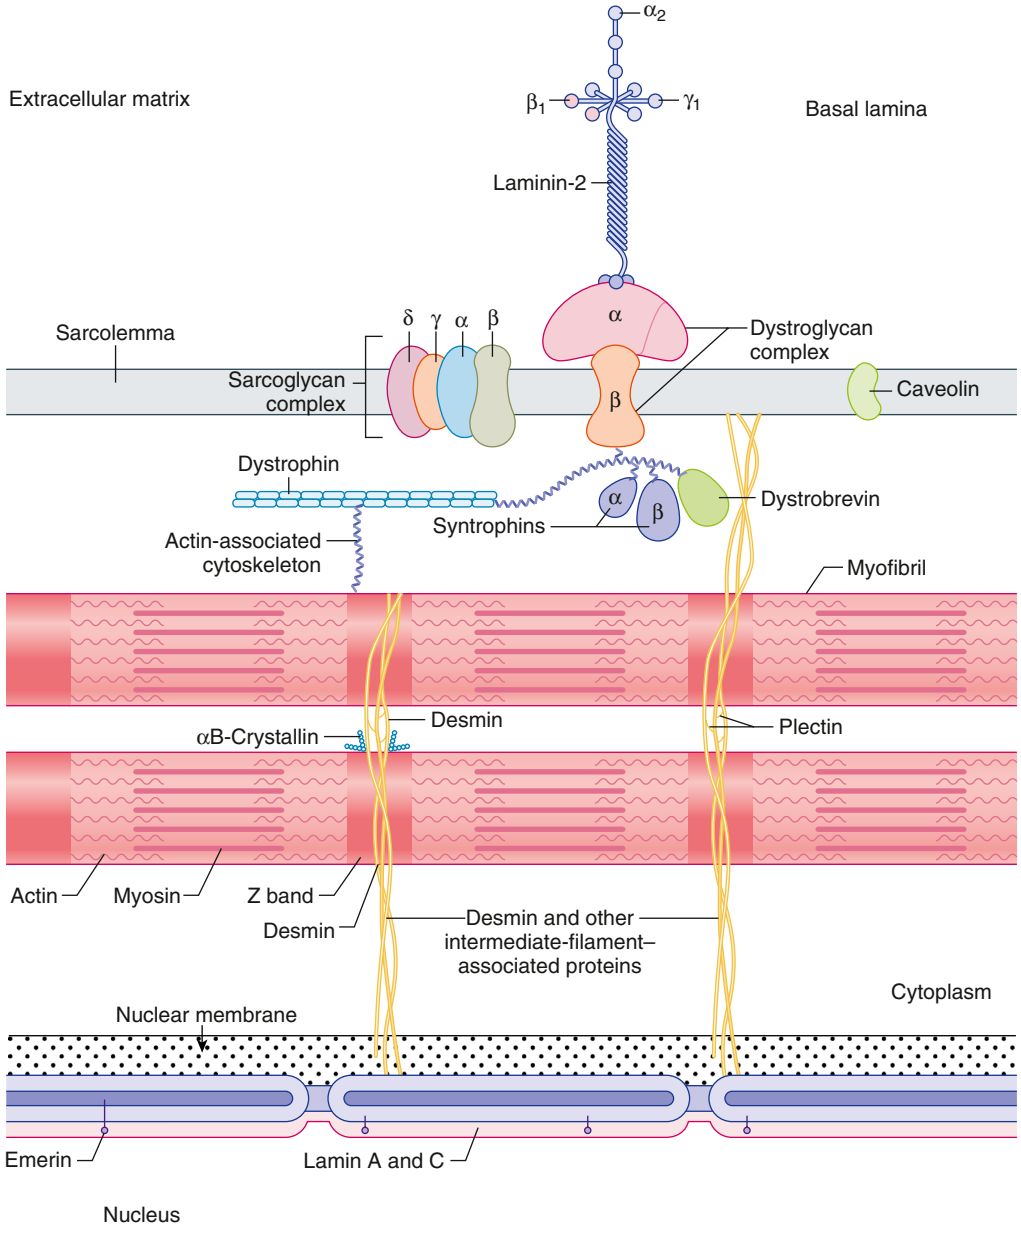
Muscle pain is another nonspecific symptom that can arise from many systemic and psychiatric conditions. Sometimes patients describe aching, stiffness, numbness, or burning as pain. Muscle diseases rarely cause diffuse, generalized, or persistent muscle pain. Muscle pain without muscle weakness

ABSTRACT

Muscle diseases, which are also called myopathies, are disorders of skeletal muscle structure or function. Myopathies can be primary and occur in isolation, or they can be part of a multisystem disorder. Many muscle diseases are inherited as autosomal dominant, autosomal recessive, X-linked, or maternal (mitochondrial) conditions. Environmental factors may precipitate myopathies. Myopathies often present with localized or diffuse muscle weakness, reduced exercise tolerance, resting or exercise-induced muscle pain, muscle enlargement or atrophy, cramps, delayed relaxation, or rarely, myoglobinuria. Exercise commonly precipitates symptoms in patients with metabolic myopathies, whereas exposure to cold and high-carbohydrate or potassium-rich food can precipitate weakness in muscle channelopathies. Neurophysiologic testing, measurement of serum creatine kinase, muscle biopsy, and genetic testing help guide the diagnosis of muscle diseases. Myopathies can cause premature death owing to neuromuscular weakness and secondary respiratory infections or to involvement of other organs in multisystem diseases. Myocardial involvement, which is particularly common in some muscle diseases, can cause heart failure or life-threatening arrhythmias.

KEYWORDS

skeletal muscle
congenital myopathy
muscular dystrophy
metabolic myopathy
mitochondrial myopathy
inflammatory myopathy
channelopathy



E-FIGURE 389-1. **Muscle structure.** (From Chinnery PF. Muscle diseases. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine,* 24th ed. Philadelphia: Elsevier; 2012.)

is often a feature of fibromyalgia (Chapter 253) or chronic fatigue syndrome. Diffuse myalgia can occur in inflammatory muscle disease such as polymyositis or dermatomyositis, vasculitis, or viral or parasitic myositis. Muscle pain precipitated by exercise usually suggests a metabolic myopathy.

Muscle cramps are involuntary painful contractions that may occur in healthy individuals. Dehydration, renal failure (Chapter 116), and electrolyte imbalances (Chapters 102, 103, 105, and 227) can also produce muscle cramps. Muscle stiffness can occur in inflammatory, metabolic, and ion-channel diseases as well as in conditions such as multiple sclerosis (Chapter 380), polymyalgia rheumatica (Chapter 250), and connective tissue diseases (Chapter 236).

Fasciculations are caused by spontaneous firing of muscle fibers that are innervated by a single motor unit. Fasciculations may occur in normal persons, in whom they are usually exacerbated by stress and increased caffeine intake. Fasciculations in association with muscle weakness suggest anterior horn cell disease. Myotonia, often described as muscle stiffness, is characterized by prolonged contraction and delayed relaxation of muscle.

Myotonia can affect limb, facial, or bulbar muscles, and it can lead to persistent limb muscle contraction, eyelid closure, or dysphagia. Myotonic dystrophy is the most common muscle disease associated with myotonia, but patients usually complain more of weakness than the myotonia. Conversely, the myotonia associated with sodium and chloride channelopathies can be disabling. Patients who describe locking of their hands but do not have objective myotonia rarely have a physical explanation for their symptoms.

Tetany is the most severe form of sustained muscle contraction. Tetany occurs in patients with hypocalcemia and hypomagnesemia (Chapter 105), and it is aggravated by metabolic or respiratory alkalosis (Chapter 104).

Severe acute muscle damage, termed *rhabdomyolysis* (Chapter 99), results in myoglobinuria that presents as dark brown or red urine. Such discoloration must be distinguished from other causes of pigmenturia (Chapter 100) such as hemolysis or porphyria.

The detailed family history should include questions about muscle disease, including specific questions about the use of canes, braces, or wheelchairs. It also should assess whether family members have had a cardiomyopathy, unexpected sudden death, diabetes, or cataracts.

Physical Examination

A full physical examination must look for signs that may suggest any of the systemic diseases that are associated with myopathies. The skin examination can give clues to systemic illness, such as the heliotrope rash of dermatomyositis (Chapter 248).

A comprehensive neurologic examination should be performed in each patient to exclude possible central or peripheral nervous system disorders (Table 389-2). Once the muscle disease is confirmed, further testing and diagnosis can be guided by the history and physical examination (Fig. 389-1). The examination begins as soon as the patient enters the examination room. Proximal leg muscle weakness may be evident if patients push themselves up on their thighs or have a waddling gait. Patients should be examined for possible facial muscle weakness or wasting, ptosis, or characteristic dysmorphic features, such as with myotonic dystrophy (Fig. 389-2), that can lead to an immediate clinical diagnosis.

Patients should be asked to rise from a squatting position and walk on their toes to assess possible calf weakness and on their heels to assess ankle dorsiflexion weakness. Patients should be asked to stand to assess posture and any evidence of rigidity or scoliosis. Joints should be moved passively to assess for contractures.

All muscle groups should be inspected for evidence of involuntary movements, atrophy, or hypertrophy. Muscles should be palpated for tenderness or unusual texture. Myotonia can be assessed by the inability to relax the muscle belly after percussion with a reflex hammer or the inability to relax the fingers from a firm grip.

Strength should be graded (Table 389-3) in each muscle group. Observing children and infants when they play with toys and how they stand up and walk usually reveals more than formal manual muscle strength testing. The pattern of muscle involvement can provide clues for the diagnosis of a specific myopathy.

DIAGNOSIS

Neurophysiologic testing, measurement of serum creatine kinase (CK), muscle biopsy, and genetic testing help guide the diagnosis of muscle diseases (see Fig. 389-1 and Table 389-4).

A complete blood count and serum levels of alanine aminotransferase, aspartate aminotransferase, and creatinine can assess possible systemic involvement. An elevated erythrocyte sedimentation rate or C-reactive protein level is found in some inflammatory myopathies and is typical of connective tissue disorders (Chapters 236 and 237). Additional tests to evaluate patients suspected of having inflammatory myopathy or connective tissue disease can include antinuclear antibodies, extractable nuclear antigens, rheumatoid factor, and antineutrophilic cytoplasmic antibodies, as well as anti-Jo-1, anti-Mi2, anti-MDA5, anti-centromere, anti-SCL-70, anti-PM/Scl-100, anti-Ku, anti-PL-7, anti-PL-12, anti-MDA5, anti-NXP-2, anti-TIF-1gamma, anti-U1 RNP, anti-U2 RNP, anti-U3 RNP, anti-SAE1, anti-SAE2, anti-EJ, anti-OJ, anti-SSA, anti-SSB, anti-3-hydroxy-3-methylglutaryl-coenzyme A reductase, or anti–signal recognition particle antibodies (Chapter 237).

The muscle isoform (MM) of CK is frequently elevated in patients with muscle disease, although a normal level is seen in metabolic myopathies and in some chronic myopathies. A mild to moderate increase in the serum CK level can occur in patients with peripheral neuropathy, radiculopathy, and anterior horn cell diseases. The serum CK level is markedly increased in dystrophinopathies, dysferlinopathy, some of the sarcoglycanopathies, α-dystroglycanopathies, and during rhabdomyolysis (Chapter 99). However, it can decline later in muscular dystrophies as the disease progresses. When the serum CK level exceeds the upper limit of normal by about 10-fold, levels of alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase also can be elevated, and some patients can be initially misdiagnosed as having hepatitis (Chapters 133 and 134) before the serum CK level is measured. The blood lactate level can be increased in patients with a mitochondrial myopathy, but a normal value does not exclude this diagnosis. In patients with acute muscle pain and/or weakness, electrolytes and thyroid function tests should be checked.

In patients who are diagnosed with dermatomyositis (Chapter 248), the evaluation should include a search for an underlying malignancy. In patients with suspected mitochondrial cytopathy, a serum and/or spinal fluid lactate level may be useful for diagnosis. In patients with suspected fatty acid β-oxidation defects, blood acylcarnitine profile may be useful for the diagnosis.

Electromyography

Electromyography (EMG) consists of nerve conduction studies, repetitive nerve stimulation, and needle examination of muscles (Chapter 366). Nerve

TABLE 389-2 CLINICAL FINDINGS DIFFERENTIATING MUSCLE FROM NERVE DISEASE

FINDING	MYOPATHY	ANTERIOR HORN CELL DISEASE	PERIPHERAL NEUROPATHY	NEUROMUSCULAR JUNCTION DISEASE
Distribution	Usually proximal and symmetrical but can be distal or asymmetrical at onset	Proximal, asymmetrical, and bulbar	Distal, symmetrical	Extraocular, bulbar, proximal limb, but sometimes distal
Atrophy	Slight early, marked late	Marked early	Moderate	Occasionally
Fasciculations	Absent	Frequent	Sometimes present	Absent
Reflexes	Lost late	Variable, can be hyperreflexic	Lost early	Normal or hyporeflexic
Pain	Variable	Absent	Variable, distal when present	Absent
Cramps	Rare	Frequent	Occasional	Absent
Sensory loss	Absent	Absent	Usually present	Absent
Serum creatine kinase	Usually elevated	Occasionally mildly elevated	Normal	Occasionally mildly elevated

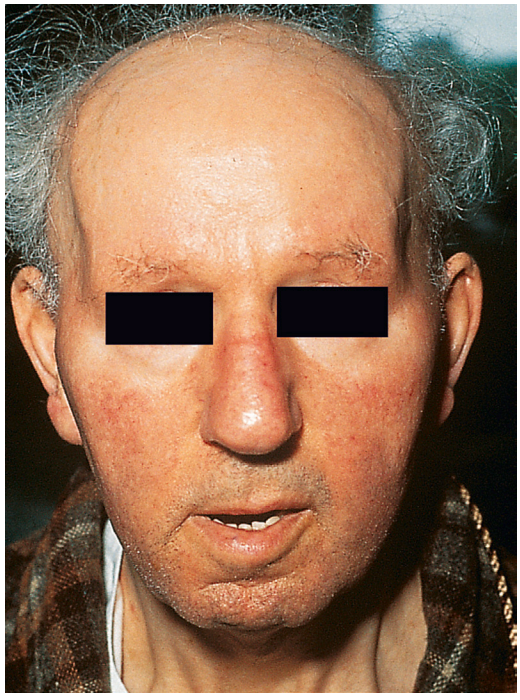

FIGURE 389-2. Myotonic dystrophy in a 50-year-old man. His appearance is typical with facial weakness, atrophy of the temporal muscles and sternocleidomastoids, and frontal baldness, which gives a monklike appearance. (From Chinnery PF. Muscle diseases. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine,* 24th ed. Philadelphia: Elsevier; 2012.)

conduction studies (Chapter 388) are normal in patients with myopathies. In myopathies, the needle examination typically shows complex, polyphasic, low-amplitude motor unit potentials. Myotonia is caused by recurrent depolarization of the muscle fiber surface membrane and has characteristic waxing and waning rhythmical discharges or fibrillation potentials during the needle examination on an EMG. Contractures are electrically silent on EMGs, but muscle cramps are associated with high-amplitude, high-frequency bursts of motor unit activity. The EMG can be normal in some focal myopathies (such as inflammatory myositis), in metabolic myopathies, and in some congenital myopathies.

TABLE 389-3 MEDICAL RESEARCH COUNCIL SCALE OF MUSCLE STRENGTH

GRADE	DEGREE OF STRENGTH
5	Normal power
4	Active movement against gravity and resistance (often subdivided into 4–, 4, and 4+)
3	Active movement against gravity, but not against resistance
2	Active movement, with gravity eliminated
1	Observable muscle contraction, but not capable of initiating movement
0	No contraction

Genetic Testing

The widespread availability of molecular genetic testing with commercial panels and whole-exome and -genome sequencing has revolutionized the approach to patients who are suspected of having hereditary muscle disease. Dystrophin genetic testing can identify the defects in dystrophin in 90 to 95% of the patients with Duchenne and Becker muscular dystrophy. The sensitivity of the whole-exome sequencing is higher if multiple affected and some unaffected family members and more than one family are analyzed at the same time. Novel genes causing muscular dystrophies are still being discovered.

Muscle Biopsy

Despite advances in genetics and molecular biology, muscle biopsy remains a key component in the diagnosis of most muscle diseases. The biopsy site should be carefully chosen from a clinically affected but not too severely involved muscle. Fresh-frozen sections of the specimens should be used for histochemical studies because even marked morphologic alterations may be

TABLE 389-4 GUIDING PRINCIPLES FOR ASSESSING MUSCLE DISEASES

1. **History**
   - Age of onset (most inherited and acquired disorders have a characteristic age of onset)
   - Rate of progression (acute suggests an acquired, often inflammatory cause)
   - Fluctuating weakness (may indicate a neuromuscular junction disorder, metabolic myopathy, or a channelopathy)
   - Relationship to exercise (may indicate metabolic myopathy or channelopathy)
   - Muscle pain (may indicate inflammatory or metabolic myopathy)
   - Relevant multisystem involvement (may indicate a mitochondrial cytopathy or myotonic dystrophy)
   - Family history (may indicate a genetically determined chronic muscle disease)
2. **Pattern of weakness**
   - Limb-girdle weakness is relatively nonspecific.
   - Inherited disorders often have specific patterns of muscle involvement.
   - Fluctuating weakness may indicate a neuromuscular junction disorder, metabolic myopathy, or channelopathy.
3. **Testing**
   - The serum creatine kinase can be normal.
   - Electromyography is often normal in metabolic myopathies.
   - All patients with muscular dystrophy should have an electrocardiogram and echocardiogram to look for cardiomyopathy and/or conduction defect.
   - Muscle magnetic resonance imaging is increasingly being used to guide muscle biopsy and may sometimes reveal diagnostic patterns of muscle involvement.
   - Some inherited muscle diseases can be diagnosed clinically and confirmed by genetic testing without requiring other investigations (e.g., myotonic dystrophy; Duchenne, Becker, and facioscapulohumeral dystrophy).
   - Muscle biopsy may reveal the cause in most cases; it identifies specific inflammatory myopathies and muscular dystrophies and often provides diagnostic clues for other muscle and neurogenetic disorders.

undetected in paraffin-embedded tissue. Immunocytochemical localization of specific proteins is useful and diagnostic in some forms of muscular dystrophies. Specific enzyme histochemistry and biochemistry can be used for metabolic myopathies. Genetic analysis of the muscle specimen can be more informative than blood specimens for mitochondrial myopathies.

Imaging

Muscle computed tomography (CT) and magnetic resonance imaging (MRI) are of limited utility for evaluating muscle diseases but can be very useful in excluding spinal cord abnormalities that may cause weakness. Some inherited myopathies are associated with patterns of atrophy and the replacement of muscle with fat. In patchy or focal inflammatory myopathy, MRI can guide muscle biopsy. Functional MRI is sometimes useful in patients with suspected mitochondrial disorders.

SPECIFIC MUSCLE DISEASES

INHERITED MUSCLE DISEASES

The four main categories of inherited muscle diseases are muscular dystrophies (E-Table 389-1), congenital myopathies (E-Table 389-2), muscle ion-channel disorders (E-Table 389-3), and metabolic myopathies (E-Table 389-4). Some gene defects cause specific phenotypes that are instantly recognizable at the bedside by an experienced clinician, but less specific phenotypes can be caused by defects in more than one gene. A systematic approach is critical for an efficient and successful investigation of these disorders.

MUSCULAR DYSTROPHIES

The term *muscular dystrophy* refers to the primary degeneration of the muscle fiber, usually associated with an increase in fatty and fibrous connective tissue.[2] The common clinical presentation is progressive muscle weakness.

DYSTROPHINOPATHIES

Duchenne and Becker muscular dystrophies are caused by mutations in the dystrophin gene, which is located on the X chromosome. Female carriers can develop variable phenotypes, including a severe Duchenne-like presentation, mild adult-onset limb-girdle weakness, asymptomatic CK elevation, and cardiomyopathy.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy is the most common inherited muscle disease, with an incidence of about 1 in 5000 male births. About one third of patients carry a de novo mutation without a family history. In most patients, a frameshift mutation in the dystrophin gene results in a complete absence of the dystrophin protein. This absence of dystrophin disrupts the mechanical link between the sarcomere and the sarcolemma, thereby causing a calcium leak that leads to necrosis of muscle fibers.

CLINICAL MANIFESTATIONS

Duchenne dystrophy typically presents in young boys who are between 2 and 5 years of age with delayed motor milestones, difficulty running, increasing falls, and enlarged calves. The disorder is relentlessly progressive and can cause a cardiomyopathy (Chapter 47) that leads to heart failure and fatal arrhythmias. Intellectual disability, learning disorders, autism, and attention-deficit/hyperactivity disorder can be associated features. By 12 years of age, most affected individuals can no longer ambulate. By the age of 20 years, most patients develop joint contractures and kyphoscoliosis that lead to further respiratory compromise.

DIAGNOSIS

Affected individuals have a 20- to 100-fold elevation of their serum CK level. Confirmation of diagnosis requires DNA analysis of the dystrophin gene. Genetic testing is positive in about 90 to 95% of patients. If genetic testing is negative, a muscle biopsy is indicated. The pathologic features are typical of a chronic myopathy. Immunostaining shows an absence of dystrophin except in revertant fibers that express dystrophin (E-Fig. 389-2).

TREATMENT

Management requires a multidisciplinary team approach,[3,4] including physical therapy to prevent contractures, the timely provision of appropriate devices and wheelchairs, and indicated medical therapies.[5]

Several phosphorodiamidate morpholino oligomers can induce exon skipping and improve symptoms in Duchenne muscular dystrophy. Eteplirsen, which is designed to skip DMD exon 51, slows the rate of decline in ambulation on a 6-minute walk test compared with placebo over 3 years of treatment compared with nonrandomized controls and has been conditionally approved by the Food and Drug Administration (FDA) to be administered once weekly as 30 mg/kg intravenous infusion.[A1] Golodirsen and viltolarsen, which are designed to induce DMD exon 53 skipping, increase dystrophin protein expression, are well tolerated, and have been conditionally approved by the FDA: golodirsen as a once-weekly 30 mg/kg intravenous infusion[A2] and viltolarsen as a once-weekly 80 mg/kg intravenous infusion.[A3] Casimersen, which is designed to induce DMD exon 45 skipping, also is beneficial and conditionally FDA-approved as a once-weekly 30 mg/kg intravenous infusion.[A4] The choice among these four options requires expert neurologic consultation.

Prednisone (0.75 mg/kg/day) prolongs the ability to ambulate despite its significant side effects (Chapter 28) and is preferable to intermittent prednisone.[A5] Both prednisone (0.75 mg/kg/day) and deflazacort (0.9 mg/kg/day) improve muscle strength, with less weight gain from deflazacort. Prednisone may also help respiratory function and slow the progression of scoliosis.

The cardiomyopathy is typically managed by using β-blockers and angiotensin-converting enzyme inhibitors (Chapter 46), the latter of which can slow the progression of myocardial fibrosis,[A6] which in turn is associated with a poorer prognosis. An orthopedic surgeon should help with monitoring of scoliosis and spinal fusion if indicated. A pulmonologist should assess and follow respiratory function, including the initiation and monitoring of noninvasive ventilation. An endocrinologist should help with monitoring bone health.

Additional gene-therapy approaches are being developed.[6] For example, removal of the mutation in the gene encoding the dystrophin protein in mice using CRISPR-Cas9 technology delivered to muscle by an adeno-associated virus can initially correct about 2% of the protein but then apparently spreads enough over time to improve strength. Recombinant AAV9 capsid carrying a truncated or shortened version of the human dystrophin gene (mini-dystrophin) under the control of a human muscle-specific promotor showed promising results in a phase Ib study.

PROGNOSIS

With ventilatory support, patients often live well into the third or even fourth decade. Chronic respiratory failure is the primary cause of death in the late 20s or early 30s, with most patients succumbing to pneumonia, heart failure, or arrhythmias.

Becker Muscular Dystrophy

Becker dystrophy is a milder form of Duchenne dystrophy caused by an in-frame mutation in the dystrophin gene.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Becker dystrophy can present in boys older than age 5 years, teenagers, or even in adults. Typical findings are symmetrical proximal weakness and prominent calf hypertrophy. Heart failure is common and may be the initial manifestation in some patients. The CK is elevated, although not to the same degree as seen in Duchenne dystrophy. Muscle biopsy findings are similar to those of Duchenne dystrophy but less severe: immunohistochemistry shows decreased dystrophin expression, and immunoblotting reveals decreased expression and/or a lower-molecular-weight dystrophin protein.

TREATMENT AND PROGNOSIS

Management is largely supportive. Corticosteroids are rarely used. Similar to Duchenne dystrophy, screening for respiratory function and cardiac monitoring is indicated. Heart transplantation (Chapter 46) has been performed in patients with severe restrictive cardiomyopathy (Chapter 47).

Many patients have a normal lifespan, although some develop respiratory failure and have a shortened lifespan owing to respiratory complications. Heart failure and arrhythmias occur late in the course of disease.

Female Carriers of Duchenne or Becker Dystrophy

Female carriers of a dystrophin gene mutation are usually totally asymptomatic. However, about 2.5 to 10% of carriers can develop symptoms, including myalgias, proximal muscle weakness, and cardiomyopathy. Rarely, they present with a Duchenne phenotype owing to an XO karyotype (Turner syndrome) or skewed X-chromosome inactivation. If a specific mutation is identified in the family, targeted DNA analysis can confirm the diagnosis. Immunostaining of the muscle specimens shows a mosaic pattern, in which some fibers express dystrophin normally and others show decreased or even absent expression. Management of symptomatic carriers is similar to the management of Duchenne and Becker dystrophy patients with similar disease severities.

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy is an autosomal dominant disorder with variable penetrance. It is the third most common dystrophy after the dystrophinopathies and myotonic muscular dystrophy, with a prevalence of about 1 in 15,000. About 95% of patients have a truncated D4Z4 tandem repeat region in chromosome 4q35.[7] The other 5% have hypomethylation of the D4Z4 region along with a mutation in the *SMCHD1* gene, which is critical for the structural maintenance of chromosome-flexible hinge-domain-containing protein 1.

CLINICAL MANIFESTATIONS

Facioscapulohumeral muscular dystrophy has a highly variable penetrance within the same family. Some gene carriers never present with clinical symptoms or signs. The muscle weakness initially affects the face, where it causes difficulty smiling or whistling. Patients then develop scapular, humeral, truncal, and lower limb weakness leading to footdrop. Scapular winging is a typical feature. Muscle involvement is often asymmetrical.

Associated symptoms can include high-frequency hearing loss and retinal telangiectasia. Rare patients with retinal vascular abnormalities can develop retinal exudation leading to retinal detachment (Chapter 391). Infants with profound facial diplegia can also have intellectual disability and intractable epilepsy.

DIAGNOSIS

The CK level ranges from normal to mildly elevated. EMG shows typical myopathic features. Muscle biopsy shows chronic myopathic changes, sometimes with an inflammatory exudate. Definite diagnosis is based on genetic testing.

TREATMENT AND PROGNOSIS

Management is supportive, and corticosteroids are of no benefit. Patients do benefit, however, from physical therapy for motion exercises for the shoulder girdle, molded ankle-foot orthoses for the footdrop, hearing aids for patients with hearing loss, and scapular fixation surgery to improve shoulder range of motion.[8] Cardiac features are not prominent, and respiratory muscle weakness is a late feature. The prognosis is highly variable, depending on the severity and age of onset. Many patients have a normal lifespan.

MYOTONIC DYSTROPHIES

Myotonic dystrophies,[9] which are the second most common inherited muscle disease, affect about 1 in 8000 of the population. The two types, DM1 and DM2, are inherited in an autosomal dominant manner. Both cause multisystem disease and can be difficult to distinguish from each other. DM1 is caused by an abnormal expansion of CTG nucleotide repeats in an untranslated region of the dystrophia myotonica protein kinase (*DMPK*) gene on chromosome 19q. DM2 is caused by an abnormal expansion of CCTG nucleotide repeats in intron 1 of the zinc finger protein 9 (*ZNF9*) gene on chromosome 3q.

CLINICAL MANIFESTATIONS

Patients typically have frontal balding, ptosis, and temporal and masseter muscle wasting. Speech is nasal in quality, and patients display a high-steppage gait owing to their distal myopathy. On neurologic examination, myotonia is seen with percussion (inability to relax the muscle after percussion with a reflex hammer), after a grip (inability to relax the fingers after a firm grip), and in the eyelids (inability to open forcibly closed eyelids). Weakness in DM1 predominantly affects facial, oropharyngeal, forearm flexor, and foot dorsiflexor muscles. In DM2, weakness is predominantly proximal, although deep finger flexors are frequently affected. Muscle pain and stiffness are common in DM2 but can be seen in DM1 as well. Systemic features include premature subcapsular lens cataracts, testicular atrophy, intellectual disability, impotence, and hypersomnolence mediated by both central and neuromuscular mechanisms. Endocrine dysfunction is common, including diabetes mellitus and thyroid abnormalities. Dysphagia and constipation are common. Progressive cardiac conduction defects can lead to sudden death. Patients may require ventilation support after general anesthesia. Women who transmit DM1 are at high risk for having a child with a severe congenital form, including hypotonia at birth, respiratory failure, failure to thrive, and globally delayed developmental milestones with mild to severe intellectual disability.

DIAGNOSIS

Classical myotonic dystrophy usually can be diagnosed clinically by a patient's essentially pathognomonic facial features (see Fig. 389-2). The CK may be normal or mildly elevated. EMG, which is useful when the diagnosis is unsuspected or unclear, reveals myopathic features and myotonic discharges. Molecular genetic analysis of the nucleotide repeats confirms the diagnosis.

TREATMENT

All patients should have an annual electrocardiogram and a Holter monitor to detect conduction system abnormalities (Chapter 49). An echocardiogram should be performed at diagnosis and repeated about every 2 to 4 years. Respiratory function testing also is usually recommended about every 2 to 4 years, and a sleep study is useful to detect nocturnal hypoventilation for symptomatic patients.

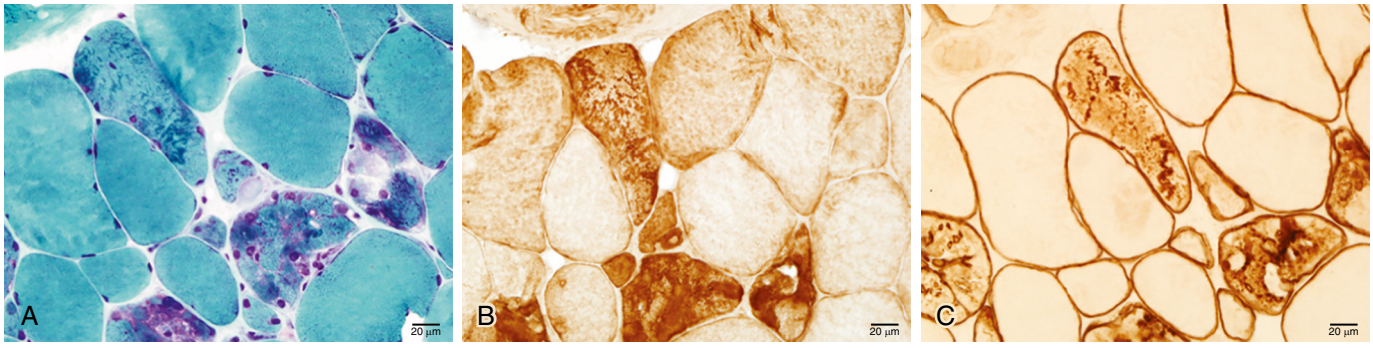
Mexiletine (150 to 200 mg three times daily) is well tolerated and can improve muscle relaxation, but it does not improve walking distance or patients' perceptions of the severity of their disease.[A7] Hypersomnolence (Chapter 374) can be treated with overnight positive-pressure ventilation. Methylphenidate (20 mg daily) may be preferable to modafinil (200 mg daily) for excessive daytime sleepiness, but neither provides dramatic results. Cardiac pacing (Chapter 54), which is frequently required, can reduce the incidence of paroxysmal atrial fibrillation. Physical therapy can help to prevent contractures.

OTHER MUSCULAR DYSTROPHIES

Limb-girdle muscular dystrophies are a diverse group of myopathies caused by gene defects or deficiencies of muscle proteins that are critical for the normal function of the muscle cell membrane and especially the dystrophin-sarcoglycan complex. Inheritance can be autosomal dominant or recessive. Although most patients have classical limb-girdle muscle weakness at the onset, some can present with distal leg muscle involvement that may initially be misdiagnosed as sensorimotor neuropathy. Some causes can be identified clinically by an experienced clinician. However, EMG can help to differentiate these conditions from neuropathies, and muscle biopsy, immunohistochemistry studies, and genetic analysis are often required to make a precise diagnosis.

Myofibrillar myopathies present with progressive distal or proximal muscle weakness and characteristic morphologic features on muscle biopsy (E-Fig. 389-3). Cardiomyopathy and neuropathy can be associated features.

Emery-Dreifuss muscular dystrophy was originally described as X-linked and was initially shown to be caused by mutations in the emerin gene, a nuclear membrane protein. However, mutations in other genes can cause a similar



E-FIGURE 389-3. **Myofibrillar myopathy. A,** Trichromatically stained section of a specimen from a patient with myofibrillar myopathy displaying abnormal fibers with hyaline deposits or amorphous material and vacuoles. Abnormal fibers show abnormal and ectopic expression for desmin (**B**) and dystrophin (**C**).

phenotype. Patients have a distinctive phenotype, including progressive joint contractures, scapuloperoneal distribution weakness, and cardiomyopathy with a progressive cardiac conduction disorder. The CK is often elevated but can be normal. Cardiac function needs to be monitored periodically. As with the dystrophinopathies, female carriers of the X-linked forms may develop weakness and cardiac disease.

Oculopharyngeal muscular dystrophy is an autosomal dominant myopathy caused by a trinucleotide repeat expansion of the poly(A)-binding protein, nuclear 1 (*PABPN1*) gene. Onset typically occurs in the fifth or sixth decade of life with dysphagia and marked ptosis. Marked distal and proximal weakness occurs later in the disease course. Surgical correction of ptosis often yields excellent results, but the dysphagia can be more difficult to manage. Patients often have a normal lifespan.

CONGENITAL MUSCULAR DYSTROPHIES

Congenital muscular dystrophies (see E-Table 389-2) are a rare group of autosomal recessive muscle diseases that present in infancy or childhood with hypotonia and muscle weakness. The main differential diagnosis is spinal muscular atrophy (Chapter 387) and congenital myasthenia (Chapter 390). Affected infants can have joint contractures, which can be severe at birth. Some have a pure muscle phenotype and survive into adulthood. Others have severe central nervous system and eye involvement, which are associated with hypoglycosylation of α-dystroglycan that may be fatal in early childhood.

CONGENITAL MYOPATHIES

Congenital myopathies (see E-Table 389-2) are rare inherited muscle diseases that are generally less severe than congenital muscular dystrophies. Most patients present at birth with hypotonia, myopathic facies, and delayed motor milestones. The weakness is usually slowly progressive. Respiratory muscle weakness can occur, and patients can present with ventilator failure at birth or insidiously in adult life. The most severely affected patients present in utero with reduced fetal movements and polyhydramnios. Muscle biopsy is diagnostic (E-Figs. 389-4 to 389-6). Patients with central core myopathy can develop malignant hyperthermia (Chapter 400).

No specific treatments are available. Management requires a multidisciplinary team approach similar to muscular dystrophies.

ION CHANNELOPATHIES

Ion channelopathies (see E-Table 389-3) are genetically determined disorders in which the muscle membrane functions abnormally. The combined prevalence of the various skeletal muscle channelopathies is about 1.1 per 100,000.[10] Each has a specific molecular cause, but the phenotypes overlap.

CHLORIDE CHANNELOPATHIES

Mutations in the muscle chloride-channel gene *CLCN1* cause autosomal dominant (Thomson) and autosomal recessive (Becker) myotonia congenita. Patients present with painless myotonia, muscle stiffness that may be slightly worse in the cold and improves with exercise (the warm-up phenomenon), muscle hypertrophy, and grip and percussion myotonia. EMG shows myotonic discharges. The myotonia responds to mexiletine (150 to 200 mg up to three times a day). Patients have a normal lifespan.

SODIUM CHANNELOPATHIES

Mutations in *SCN4A*, which is the voltage-gated sodium-channel gene, cause a range of autosomal dominant phenotypes, including hyperkalemic periodic paralysis, paramyotonia congenita, and potassium aggravated myotonia. Periodic paralysis is typically precipitated by sustained exercise that leads to weakness during the rest period, by potassium-rich food, or sometimes by emotional stress or cold. The attacks can persist for hours, during which the patient can be quadriplegic with depressed tendon reflexes but normal sensation, eye movements, and respiration. The serum potassium level may be high or normal during the attack. The physical examination is usually normal between attacks, but some patients develop fixed proximal weakness later in the disease. In patients with paramyotonia, the muscle stiffness paradoxically increases with exercise and is often painful. Cold sensitivity is typically more extreme than that seen in myotonia congenita, and cold can precipitate the muscle weakness. The diagnosis is made clinically, although patients with fixed proximal muscle weakness, which can be confused with other myopathies, have vacuolar changes and sometimes tubular aggregates on muscle biopsy. For both phenotypes, management involves avoidance of precipitating factors such as cold or strenuous exercise. If the myotonia is disabling, medications that act on sodium channels such as dichlorphenamide (50 to 200 mg daily), acetazolamide (250 mg twice daily), mexiletine (150 mg three times a day), phenytoin (300 to 600 mg daily), and carbamazepine (400 to 800 mg daily) can be considered. Life expectancy is normal.

CALCIUM CHANNELOPATHIES

Hypokalemic periodic paralysis is usually caused by autosomal dominant mutations in the voltage-dependent calcium channel gene *CACNA1S* but in about 10% of cases is caused by dominant mutations in *SCN4A*. The attacks of weakness, which are usually more severe and prolonged than in hyperkalemic period paralysis, generally persist for hours to days before gradually resolving. Attacks occur spontaneously or during prolonged rest after vigorous exercise and also can be precipitated by a high-carbohydrate meal. The serum potassium level is reduced or low-normal during the attack. Avoidance of high carbohydrate loads and treatment with acetazolamide (125 to 1000 mg/day) or dichlorphenamide (50 to 200 mg/day)[A8] are effective in hypokalemic periodic paralysis. Patients may develop permanent muscle weakness if they have frequent attacks.

OTHER FORMS OF PERIODIC PARALYSIS AND MUSCLE STIFFNESS

Periodic paralysis can occur in a wide range of metabolic and electrolyte disorders (Table 389-5).[11] Mutations in the *KCNJ2* gene, which encodes the inward rectifier potassium channel Kir2.1, cause *Andersen-Tawil syndrome*, an autosomal dominant, usually hypokalemic, periodic paralysis that is associated with distinctive facial features, including hypertelorism and low-set ears, as well as a propensity for cardiac arrhythmias. Treatment includes acetazolamide (250 mg twice daily) and dichlorphenamide. For patients with sulfa allergy, potassium-sparing diuretics such as spironolactone (25 to 100 mg/day) or triamterene (25 to 100 mg/day) can be used. The patients should be treated as indicated for the cardiac arrhythmia and prolonged QT interval (Chapter 53). Despite successful treatment, many patients have long-term changes with fat replacement detectable by MRI.[12]

Brody disease, an autosomal recessive disorder caused by mutations in the SR calcium ATPase gene (*ATP2A1*), is characterized by exercise-induced muscle stiffness that is electrically silent on EMG. There are case reports of treatment with dantrolene, verapamil, or nifedipine with varying success.

Neuromyotonia (Isaac syndrome) is an autoimmune disorder associated with peripheral nerve hyperexcitability. It is caused by voltage-gated potassium-channel antibodies and is part of a spectrum of disorders, including limbic encephalitis. Oral immunomodulatory therapy, intravenous immunoglobulin, plasmapheresis, and symptomatic therapy with carbamazepine or phenytoin have been used with varying response. *Rippling muscle syndrome*, which can be caused by mutations in the *CAV3* gene, is characterized by rippling muscles triggered by exercise or percussion. Rippling muscle syndrome and neuromyotonia

can be paraneoplastic phenomena, and a search for malignancy should be considered in these patients.

METABOLIC MYOPATHIES

Metabolic myopathies (see E-Table 389-4) are caused by enzyme defects that affect the three principal stages of muscle metabolism: (1) carbohydrate disorders due to a defect of glucose-glycogen metabolism; (2) disorders of fatty acid oxidation; and (3) disorders of mitochondrial oxidative phosphorylation. Muscle dysfunction can be acute, recurrent, and reversible, but the exercise intolerance can cause progressive weakness or even rhabdomyolysis (Chapter 99).

DISORDERS OF CARBOHYDRATE METABOLISM

Because glucose and glycogen are the primary energy sources for muscle contraction, any defects of glucose-glycogen metabolism cause muscle pain, cramps, contracture, and weakness within the first 30 minutes of exercise. The most common form is myophosphorylase deficiency (Chapter 191), and other forms are extremely rare. Most of these disorders are inherited autosomal recessively, although phosphoglycerate kinase deficiency is X-linked. Patients also note exercise intolerance and become deconditioned. Severe episodes are associated with very high CK levels, rhabdomyolysis, and myoglobinuria.

Phosphorylase Deficiency

Phosphorylase deficiency (McArdle disease, type IV glycogenosis) typically presents with muscle pain or cramps after short bursts of exercise. Some patients present with recurrent rhabdomyolysis. Persistent exercise beyond 30 minutes leads to the "second-wind" phenomenon, when fatty acids become the primary source of muscle energy. Clinical examination and the CK can be normal between the attacks, although some patients develop fixed proximal muscle weakness with myopathic features on EMG. Histochemical and enzyme analysis of muscle confirms the diagnosis. A high-protein diet and 37 g or 75 g of oral sucrose shortly before exercise and graded exercise may improve symptoms, but patients are at risk for developing contractures. The life expectancy is normal.

Acid Maltase Deficiency

Acid maltase deficiency (type II glycogenosis, α-1,4-glucosidase), also called Pompe disease, may present in infancy as a very severe generalized muscle disease that is fatal before age 2 years, as a juvenile variant that causes muscle weakness and death by the second or third decade owing to respiratory failure, or as an adult-onset form that presents with limb-girdle muscle weakness or sometimes with respiratory failure (Chapter 192). In each type, EMG reveals myotonic discharges. Abnormal glycogen storage and acid phosphatase–positive vacuoles are seen on muscle biopsy. The disorder can be diagnosed by measuring the enzyme activity in leukocytes or in muscle, but the use of dried blood samples to measure enzyme activity is increasingly becoming the standard practice. Mutation analysis is also clinically available. Enzyme replacement therapy appears promising in children and in the late-onset form.[A9]

DISORDERS OF FATTY ACID METABOLISM

After about 30 minutes of exercise, when the muscle glycogen reserves become exhausted, fatty acids become the principal source of muscle energy. Fatty acid metabolism involves the transport of fatty acids from the serum into the muscle and mitochondria, where both carnitine and carnitine palmitoyltransferase are key components of the β-oxidation pathway.

Fatty acid oxidation disorders can present with a proximal myopathy, exercise intolerance, muscle pain, rhabdomyolysis, and cardiomyopathy. Other features can include neuropathy, pigmentary retinopathy, recurrent hypoketotic hypoglycemia, seizures, and intellectual disability. There may be a family history of sudden unexpected death syndrome. The most common fatty acid oxidation defect is *medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. Carnitine palmitoyltransferase I deficiency* presents in childhood with an encephalopathy and liver failure associated with hypoglycemia and a high blood ammonia during metabolic crises. *Carnitine palmitoyltransferase II deficiency* can present as a fatal infantile-onset form or, more commonly, between the first and sixth decade of life with muscle pain, exercise intolerance, and myoglobinuria, typically after a long period of fasting or sustained exercise.

Carnitine deficiency can be primary or secondary. *Primary carnitine deficiency* causes myopathy, cardiomyopathy, and encephalopathy in association with hypoketotic hypoglycemia, although pure muscle presentations have been described. The diagnosis can be made by finding a low blood level, although prominent fat deposition in muscle is another clue. Other metabolic myopathies that can cause a secondary carnitine deficiency include disorders of β-oxidation and mitochondrial oxidative phosphorylation and may cause similar symptoms as the primary carnitine deficiency. Analysis of serum acylcarnitines, urine organic acids, and urine acylglycines and specific enzyme assays in fibroblasts can help to pinpoint the enzyme defect.

TREATMENT

The general treatment approach is avoidance of precipitating factors, such as prolonged fasting or prolonged exercise. Carbohydrate intake is advised before exercise, and patients should be prescribed a high-carbohydrate, low-fat diet with frequent feedings. Both primary and secondary carnitine deficiencies respond well to oral carnitine replacement (50 to 200 mg/kg/day in divided doses). Some patients have a multiple acyl-coenzyme A dehydrogenase deficiency (also called trifunctional enzyme deficiency, or glutaric aciduria type II), which responds well to riboflavin (100 mg daily).

DISORDERS OF MITOCHONDRIAL OXIDATIVE PHOSPHORYLATION

Disorders of mitochondrial oxidative phosphorylation (see E-Table 389-4), which are among the most common causes of inherited metabolic diseases, can present with isolated myopathy but often are multisystemic with cardiac involvement, diabetes mellitus, and both central and peripheral neurologic features.[13] Abnormal fatigability or exercise intolerance is a frequent complaint. Common CNS manifestations include epilepsy, migraine, strokelike episodes, myoclonus, ataxia, neuropathy, pigmentary retinopathy, dementia, and psychomotor regression.

Mitochondrial oxidative phosphorylation requires five respiratory chain complexes that are located on the inner mitochondrial membrane. Mitochondrial dysfunction results in energy deficits, which can lead to organ failure. Mitochondrial proteins can be coded by mitochondrial DNA (mtDNA), which is maternally inherited, and nuclear DNA, which can be inherited in an autosomal dominant, recessive, or X-linked manner. Phenotypic presentation of mtDNA defects depends on heteroplasmy, which is the amount and tissue distribution of the mutant mtDNA. If the amount of heteroplasmy exceeds a certain threshold, symptoms become apparent. Mitochondrial DNA disorders affect the structure or amount of the respiratory chain proteins, whereas nuclear DNA disorders can affect the proteins, the assembly of the respiratory chain, or the maintenance of mtDNA.

CLINICAL MANIFESTATIONS

Mitochondrial diseases should be considered in all patients who have a complex multisystemic myopathy, especially patients with neuromuscular, ocular, and endocrine involvement.[14]

Mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS) is most frequently caused by a point mutation of mtDNA (m.3243 A>G). Patients can have myopathy, cardiomyopathy, strokelike attacks, and encephalopathy. Some patients have one or only a few of these characteristics, some only have diabetes and deafness, and some only have cardiomyopathy.

Myoclonic epilepsy with ragged-red fibers (MERRF) is usually caused by a point mutation of mtDNA (m.8344 A>G). It presents with a proximal myopathy associated with slowly progressive ataxia, epilepsy, peripheral neuropathy, and myoclonus.

Leber hereditary optic neuropathy (Chapter 392) predominantly affects young adult men, more than 95% of whom have mtDNA point mutations in m.3460 G>A, m.11778 G>A, or m.14484 T>C. Patients develop subacute bilateral visual failure in both eyes within 2 to 3 months.

Chronic progressive external ophthalmoplegia with ptosis and gradual limitation of eye movements is seen in up to 20% of mitochondrial disorders.[15] About 95% of patients have sporadic mtDNA point mutations or deletions, but the disease can be inherited as either an autosomal dominant or recessive trait. Mutations in the *POLG* gene, which encodes the mitochondrial polymerase γ, are the most common causes of autosomal dominant or recessive progressive external ophthalmoplegia. *Kearns-Sayre syndrome* (Chapter 392) is characterized by the triad of external ophthalmoplegia, retinitis pigmentosa, and onset before the age of 20 years plus at least one of the following: heart block, cerebellar ataxia, or cerebrospinal fluid protein greater than 100 mg/dL. Kearns-Sayre syndrome is usually sporadic and caused by a single deletion of mtDNA.

Mitochondrial DNA depletion syndromes can present in the neonatal period or infancy with subacute necrotizing encephalomyopathy (*Leigh syndrome*), hepatorenal failure, cardiomyopathy, and severe lactic acidosis. Children with

Pearson syndrome, which is caused by accumulation of mtDNA deletions, typically present with pancytopenia, sideroblastic anemia, and exocrine pancreatic failure. *Primary coenzyme Q10 (ubiquinone) deficiency* is a rare autosomal recessive disorder that can present with encephalopathy, lipid storage myopathy, myoglobinuria, seizures, and cerebellar ataxia or as an isolated nephrotic syndrome or an isolated myopathy.

DIAGNOSIS, TREATMENT, AND PROGNOSIS

The investigation of suspected mitochondrial disorders involves a systematic screen for multisystem complications, especially diabetes and cardiomyopathy; muscle biopsy to look for ragged red fibers, cytochrome c oxidase deficiency, or biochemical evidence of respiratory chain dysfunction; search for mitochondrial deletion or depletion in muscle; and molecular genetic tests. Some primary mtDNA defects are not detectable in blood, so skeletal muscle is often required for the biochemical and genetic tests. For example, diagnosis of primary coenzyme Q10 (CoQ10) deficiency is made by measuring CoQ10 in muscle but not in blood.

Patients with primary CoQ10 deficiency can respond dramatically to CoQ10 supplementation (30 mg/kg/day in children and up to 2400 mg/day in adults in three divided doses). Vitamins and cofactors, including thiamine, riboflavin, and CoQ10, have shown varying degrees of benefit in different mitochondrial diseases. Management is largely supportive with monitoring and treatment of complications. Prognosis varies depending on the phenotype, ranging from the relatively normal life expectancy with chronic external ophthalmoplegia to a relatively rapid demise with Leigh syndrome.

OTHER METABOLIC AND TOXIC MYOPATHIES

Myopathy can complicate many metabolic disorders, including hypothyroidism (Chapter 207), Addison disease (Chapter 208), hyperaldosteronism (Chapter 208), hyperparathyroidism (Chapter 227), vitamin D deficiency (Chapter 226), and liver and renal failure (Chapters 116 and 139). The myopathy is often subtle, the CK level and EMG are often normal, and the muscle biopsy may be nonspecifically abnormal.

Alcohol (Chapters 364 and 384) and many drugs cause myopathy (Table 389-6) with proximal muscle weakness, muscle pain, and exercise intolerance. The CK and EMG can be normal, and muscle biopsy findings may be nonspecific. The diagnosis may depend on the resolution of symptoms after the toxic agent is removed. Perhaps the most commonly incriminated medications are statins (Chapter 190), which can cause mild muscle symptoms or a severe autoimmune myopathy with a symmetrical proximal weakness, muscle pain, a markedly increased CK level, and, rarely, myoglobinuria. The presence of anti-HMG-CoA reductase antibodies is diagnostic.[16] Steroid-induced myopathy (Chapter 28) is characterized by symmetrical weakness predominantly of proximal muscles.[17]

INFLAMMATORY MUSCLE DISEASES

Inflammatory or immune myopathies are a heterogeneous group of acquired muscle diseases (E-Table 389-5) that usually present with muscle weakness and exercise intolerance, with or without pain (Chapter 248).[18,19] Careful evaluation can help distinguish among the most common possible causes (Table 389-7). Most patients have an elevated CK level and an abnormal EMG. Muscle biopsy shows an inflammatory infiltrate. However, the inflammatory process can be patchy and missed on the EMG or muscle biopsy, especially if the specimen is small or if a clinically unaffected muscle is biopsied. Similarly, a short period of corticosteroid therapy can mask the findings. MRI guidance can help to identify high-yield locations for muscle biopsy. Inflammatory exudates are usually mild or absent in necrotizing autoimmune myopathies.

Systemic diseases associated with an inflammatory myopathy[20] include polymyositis, dermatomyositis, inclusion body myositis (Chapter 248),[21] systemic lupus erythematosus (Chapter 245), mixed connective tissue disease (Chapter 62), Sjögren syndrome (Chapter 247), rheumatoid arthritis (Chapter 243), and sarcoidosis (Chapter 83). Systemic viral illnesses and other infectious microorganisms frequently cause muscle pain and an elevated CK, which rarely are major clinical problems.

SARCOPENIA AND MUSCLE WASTING

Muscle wasting is a common problem in elderly people (Chapter 24), partly related to hormonal changes and largely related to underuse. Critically ill patients rapidly lose muscle owing to inactivity and reduced protein synthesis, with some potential to slow this process with protein-calorie nutrition (Chapter 97).[22] Sarcopenia is also a prominent feature of many cancers, end-stage heart failure (Chapter 45), renal failure (Chapter 117), and eating disorders (Chapter 200).

390 DISORDERS OF NEUROMUSCULAR TRANSMISSION

HENRY J. KAMINSKI

DEFINITION

The clinical recognition of neuromuscular transmission disorders (Table 390-1) is critically important because all are treatable. Afflicted patients have the potential to improve substantially or even return to normal function, whereas undiagnosed or untreated disease leads to severe morbidity and death. Each of these disorders compromise the postsynaptic potential, thereby reducing the force generated by muscles. Myasthenia gravis and Lambert-Eaton syndrome are autoimmune diseases. The much less common genetic disorders mimic the autoimmune diseases clinically but do not respond to immunotherapies. Toxic and infectious disorders of neuromuscular transmission can be more easily identified because of coexistent autonomic findings and a history of exposure, which sometimes is obvious but sometimes requires a detailed evaluation.

EPIDEMIOLOGY

All neuromuscular transmission disorders are rare. Myasthenia gravis has an estimated annual incidence of about three to four per million, with a prevalence of 200 to 400 per million. Myasthenia gravis occurs more commonly after age 50 years[1] and in women, but at least 30% of patients, especially older patients, are men. Japanese and Chinese populations appear to have higher frequencies of myasthenia gravis restricted to the ocular muscles, whereas muscle-specific kinase myasthenia gravis appears to be more common in Blacks compared with Whites and is more common in European countries closer to the equator. The estimated prevalence of Lambert-Eaton syndrome is about one-tenth that of myasthenia gravis. Congenital myasthenic syndromes have an estimated prevalence of 10 per million. Botulism cases depend on outbreaks of foodborne infections, with 100 cases, about 25% of which are foodborne, reported annually in the United States.[2] Toxic exposures to organophosphates and other chemicals are sporadic and vary based on the scale of exposure. Except for myasthenia gravis, these diseases are sufficiently uncommon that most information is based on expert opinion, retrospective studies, or small case series.

PATHOBIOLOGY

Neuromuscular transmission involves propagation of an action potential along a motor nerve, thereby leading to an electrical potential change at the nerve terminal and the triggering of calcium influx through voltage-gated calcium channels. The calcium influx signals a series of synaptic proteins to fuse the synaptic vesicles that contain acetylcholine to the neuronal cell membrane, thereby allowing their contents to be released into the narrow cleft between the nerve ending and the postsynaptic muscle surface. Acetylcholine rapidly diffuses across the cleft and binds to highly concentrated acetylcholine receptors, which trigger the ion channel to open and generate an end plate potential that, if of adequate magnitude, activates an action potential, which then propagates along the muscle fiber to prompt muscle contraction. The postsynaptic folds and concentration of sodium channels at their base serve to increase the postsynaptic potential. Diffusion of acetylcholine and its hydrolysis by acetylcholinesterase, which is anchored to the basal lamina of the synaptic cleft, serve to terminate postsynaptic activation (E-Fig. 390-1).

Disorders of neuromuscular transmission produce clinical manifestations by compromising or eliminating the difference between the postsynaptic potential

390 DISORDERS OF NEUROMUSCULAR TRANSMISSION

HENRY J. KAMINSKI

DEFINITION

The clinical recognition of neuromuscular transmission disorders (Table 390-1) is critically important because all are treatable. Afflicted patients have the potential to improve substantially or even return to normal function, whereas undiagnosed or untreated disease leads to severe morbidity and death. Each of these disorders compromise the postsynaptic potential, thereby reducing the force generated by muscles. Myasthenia gravis and Lambert-Eaton syndrome are autoimmune diseases. The much less common genetic disorders mimic the autoimmune diseases clinically but do not respond to immunotherapies. Toxic and infectious disorders of neuromuscular transmission can be more easily identified because of coexistent autonomic findings and a history of exposure, which sometimes is obvious but sometimes requires a detailed evaluation.

EPIDEMIOLOGY

All neuromuscular transmission disorders are rare. Myasthenia gravis has an estimated annual incidence of about three to four per million, with a prevalence of 200 to 400 per million. Myasthenia gravis occurs more commonly after age 50 years[1] and in women, but at least 30% of patients, especially older patients, are men. Japanese and Chinese populations appear to have higher frequencies of myasthenia gravis restricted to the ocular muscles, whereas muscle-specific kinase myasthenia gravis appears to be more common in Blacks compared with Whites and is more common in European countries closer to the equator. The estimated prevalence of Lambert-Eaton syndrome is about one-tenth that of myasthenia gravis. Congenital myasthenic syndromes have an estimated prevalence of 10 per million. Botulism cases depend on outbreaks of foodborne infections, with 100 cases, about 25% of which are foodborne, reported annually in the United States.[2] Toxic exposures to organophosphates and other chemicals are sporadic and vary based on the scale of exposure. Except for myasthenia gravis, these diseases are sufficiently uncommon that most information is based on expert opinion, retrospective studies, or small case series.

PATHOBIOLOGY

Neuromuscular transmission involves propagation of an action potential along a motor nerve, thereby leading to an electrical potential change at the nerve terminal and the triggering of calcium influx through voltage-gated calcium channels. The calcium influx signals a series of synaptic proteins to fuse the synaptic vesicles that contain acetylcholine to the neuronal cell membrane, thereby allowing their contents to be released into the narrow cleft between the nerve ending and the postsynaptic muscle surface. Acetylcholine rapidly diffuses across the cleft and binds to highly concentrated acetylcholine receptors, which trigger the ion channel to open and generate an end plate potential that, if of adequate magnitude, activates an action potential, which then propagates along the muscle fiber to prompt muscle contraction. The postsynaptic folds and concentration of sodium channels at their base serve to increase the postsynaptic potential. Diffusion of acetylcholine and its hydrolysis by acetylcholinesterase, which is anchored to the basal lamina of the synaptic cleft, serve to terminate postsynaptic activation (E-Fig. 390-1).

Disorders of neuromuscular transmission produce clinical manifestations by compromising or eliminating the difference between the postsynaptic potential

Known targets for autoantibodies

- Acetylcholine receptor (AChR)
- Muscle-specific kinase (MuSK)
- Lipoprotein-related receptor protein 4 (LRP4)
- Voltage-gated calcium channel (VGCC)
- Voltage-gated potassium channel (VGKC)

Main targets for genetic defects

- Acetylcholine receptor (AChR)
- Receptor aggregating protein at the synapse (Rapsyn)
- Choline acetyltransferase (CHAT)
- Acetylcholinesterase (AChE)
- DOK7

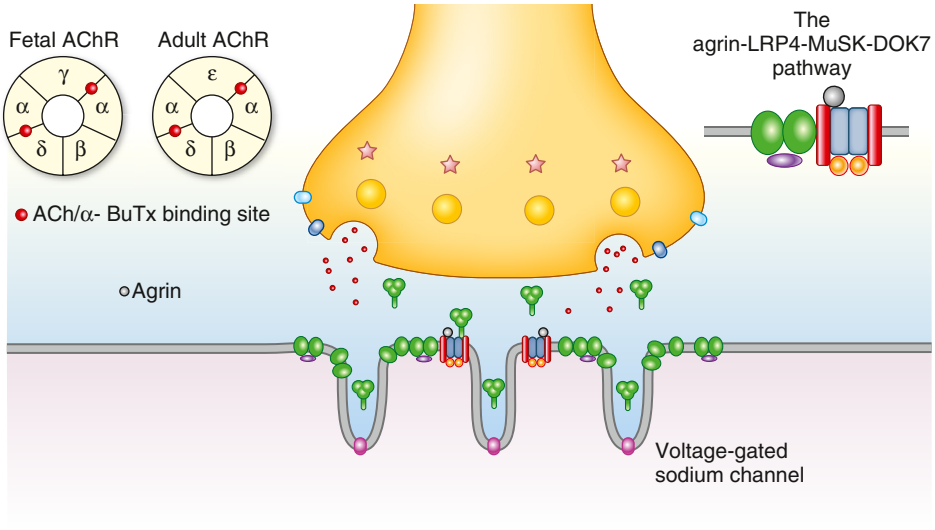

FIGURE E-E- 390-1. Diagrammatic representation of the neuromuscular junction, indicating the ion channels, receptors, enzymes, and associated proteins that are the most frequent targets for autoimmune diseases (left) or mutations in genetic disease (right). The acetylcholine (ACh) receptor (AChR) exists in fetal and adult isoforms as illustrated at *top left*. The replacement of the fetal form by the adult form takes place toward the end of gestation in humans. The agrin-lipoprotein–related receptor protein 4–muscle-specific kinase–downstream of kinase 7 (DOK7) pathway associated with AChRs on the postsynaptic membrane is illustrated at *top right*. α-BuTx = α-bungarotoxin, the snake toxin that binds with high specificity to the two ACh binding sites on the AChRs. ABSTRACT

Disorders of neuromuscular transmission can be caused by autoimmune, genetic, infectious, and toxic conditions. The clinical presentations of each share common features of fatigable weakness, which may be life-threatening, and have a propensity to involve the ocular muscles. The most common of these rare diseases is myasthenia gravis, which is caused by autoantibodies directed against the nicotinic acetylcholine receptor and other postsynaptic proteins of the neuromuscular junction. In Lambert-Eaton syndrome, autoantibodies attack presynaptic voltage-gated calcium channels and compromise the release of acetylcholine. For both of these disorders, immunotherapies can moderate the severity of the weakness but also can have serious adverse effects. Neuromyotonia, which is phenotypically distinct, manifests as hyperexcitable muscles caused by antibodies to potassium-gated potassium channels. A range of mutations lead to congenital myasthenic syndromes, which are phenotypically similar to myasthenia gravis and Lambert-Eaton syndrome and can be treated by drugs that enhance neuromuscular transmission. Botulism, which manifests as rapidly progressive weakness in association with autonomic disturbances, requires rapid identification to institute antitoxin therapy. A number of neurotoxins can compromise neuromuscular transmission and produce rapid paralysis and death. The challenge for the clinician lies in recognition of these rare diseases so that tailored treatments can be instituted.

organophosphates

TABLE 390-1 DISORDERS OF NEUROMUSCULAR TRANSMISSION

DISEASE	TARGET	PATHOBIOLOGY
AUTOIMMUNE		
Myasthenia gravis	AChRs	Antibodies to AChR in 85% reduce AChR numbers and EPP amplitude
Transient neonatal myasthenia	MuSK	Antibodies to MuSK in 5 to 8% reduce MuSK–LRP4 binding
	LRP4	Antibodies to LRP4 in a small proportion of patients reduce LRP4–agrin binding
	AChRs MuSK	Maternal antibodies cause transient disease in neonate
Arthrogryposis	Fetal AChR	Maternal antibodies that inhibit fetal AChR function resulting in paralysis in the fetus in utero, leading to multiple joint contractures
Lambert-Eaton myasthenic syndrome	VGCCs	Antibodies to VGCC in 90% reduce VGCC numbers, acetylcholine release and EPP amplitude
Acquired neuromyotonia	VGKC-complex	Antibodies to VGKC-complex (mainly CASPR2) in 40% lead to increased and spontaneous ACh release
GENETIC		
Presynaptic	ChAT, ChT, SYT2, SNAP25	Different mutations (mostly recessive) reduce acetylcholine release. ChAT mutations are the most common
Synaptic	ColQ, laminin ß2	Mutations in the collagen tail (*COLQ*) that anchor AChE at the neuromuscular junction cause absence of AChE Rare mutations of LAMB2 reduce ACh release and EPP amplitude
	AChR	Recessive mutations in AChR-subunits (mostly in the ε-subunit) cause reduced AChR expression
Postsynaptic	AChR	Dominant or recessive mutations in AChR-subunits cause kinetic defects: "slow" and "fast" channel syndromes
	$Na_v1.4$	Mutations in SCN4A sodium channel reduce muscle fiber excitability
Defects in end-plate development and maintenance	Rapsyn, DOK7, agrin, MuSK, LRP4	Recessive mutations cause structural alterations of the end plate. DOK7 and rapsyn defects are the most common
Glycosylation defects	GFPT1, DPAGT1, ALG2, ALG14	Recessive mutations cause glycosylation defects of end-plate proteins. GFPT1 defect is the most common
Arthrogryposis, multiple pterygium, Escobar syndrome	Rapsyn, AChR δ- and γ-subunits, DOK7, MuSK, GFPT1	Recessive mutations cause a prenatal defect of neuromuscular transmission with fetal akinesia
NEUROTOXIC		
Botulism	SNARE (SNAP) receptor) proteins	Botulinum toxin gains entry into the presynaptic motor nerve and cleaves proteins involved in ACh release mechanism
Envenomation following bites from snakes, spiders, scorpions, etc.	Varied sites of action	Neurotoxins specific for VGCCs, VGKCs, AChE, AChRs, voltage-gated sodium channels, and other targets are frequent in many animal venoms and generally inhibit function
Drugs and insecticides (unintentional or intentional poisoning)	Varied sites of action	Muscle relaxants and other drugs Many antibiotics and quinine-related drugs can alter neuromuscular transmission at high dose Organophosphates block AChE and have complicated acute and chronic actions (Novichok, common pesticides)

AChE = acetylcholinesterase; AChR = acetylcholine receptor; ALG2 = alpha-1,3-mannosyl transferase; ALG14 = uridine diphosphate-*N*-acetylglucosaminyl-transferase subunit; CASPR2 = contactin-associated protein 2; ChAT = choline acetyltransferase; ChT = high-affinity choline transporter 1; ColQ= collagen-like tail of acetylcholinesterase; DOK7 = downstream of kinase 7; DPAGT1 = dolichyl-phosphate *N*-acetylglucosaminephosphotransferase 1; EPP = end-plate potential; GMPPB = guanosine diphosphate mannose pyrophosphorylase B; GFPT1 = glutamine fructose-6-phosphate transaminase; LRP4 = low-density lipoprotein-related receptor protein 4; MuSK = muscle-specific kinase; $Na_v1.4$ = muscle sodium channel; SCN4A = sodium voltage-gated channel alpha subunit 4; SNAP25 = synaptosomal nerve-associated protein 25; SYT2 = synaptotagmin 2; VGCC = voltage-gated calcium channel; VGKC-complex = voltage-gated potassium channel and associated proteins.

Reproduced from Evoli A, Vincent A. Disorders of neuromuscular transmission. In: Goldman L, Schafer AI (Eds.). *Goldman-Cecil Medicine*. Philadelphia: Elsevier; 2020:2509-2515.

and the minimum magnitude action potential that is necessary to signal muscle contraction. In myasthenia gravis, autoantibody–mediated injury of the postsynaptic surface leads to a reduction of acetylcholine receptors; if severe enough, this reduction will lead to such a low postsynaptic potential that an action potential cannot be generated. In contrast, Lambert-Eaton syndrome and botulinum toxin reduce the release of acetylcholine, thereby leading to a compromised activation of the normal postsynaptic surface. Congenital myasthenic syndromes and toxins compromise neuromuscular transmission by a variety of mechanisms.

MYASTHENIA GRAVIS

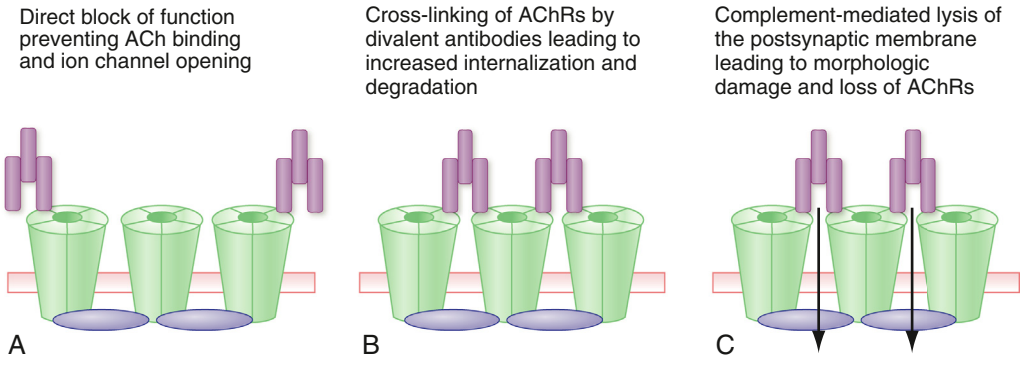
PATHOBIOLOGY

Myasthenia gravis is an autoimmune disorder caused by antibodies that are directed at postsynaptic proteins, primarily the skeletal muscle nicotinic acetylcholine receptors, muscle-specific kinase, lipoprotein receptor–related protein-4, and perhaps other autoantigens. Antibodies to the acetylcholine receptor act through activation of complement, thereby leading to destruction of the post-junctional membrane; antigenic modulation by cross-linking receptors and removal of the acetylcholine receptors from the muscle membrane; and blockade of the function of the acetylcholine receptors (E-Fig. 390-2). Antibodies to muscle-specific kinase are primarily immunoglobulin (Ig)G4 and act by inhibiting the signals that lead to the concentration of acetylcholine receptors on the postsynaptic surface. The activity of low-density lipoprotein receptor-related protein 4 antibodies is less well understood, but they likely also interfere with signals that maintain the integrity of the neuromuscular junction. Other putative antigenic targets include agrin, cortactin, and other proteins that are concentrated in the neuromuscular junction.

Myasthenia gravis consists of distinct subgroups: acetylcholine receptor antibody-positive, early-onset disease; acetylcholine receptor antibody–positive, late-onset disease, which generally occurs after age 50 years; muscle-specific kinase antibody-positive; thymoma-associated myasthenia gravis; and seronegative myasthenia gravis without detectable autoantibodies. Patients with early-onset myasthenia gravis are more often women with thymic hyperplasia, whereas the late-onset patients skew toward being men with an atrophic thymus. In about 10% of patients, and especially in men, thymomas trigger myasthenia gravis, but removal of the thymoma does not cure the myasthenia gravis. Women with early-onset myasthenia gravis are more likely to be human leukocyte antigen (HLA)-A1, B8, or DRw3-positive, whereas men with late-onset disease are more likely to have HLA-A3, B7, or DRw2.1.

Myasthenia gravis has a genetic predisposition, with close to 5% of patients having a family member with the disease. Twin studies indicate a heritability index of 0.65 for myasthenic gravis, similar to that of Alzheimer disease. Little is understood about whether environmental factors lead to myasthenia gravis.

Across all subgroups, autoantibodies are produced by B cells, supported by T cells and pro-inflammatory cytokines, but with largely unknown triggers, and the mechanisms that maintain autoreactive B cells are poorly characterized. In patients with early-onset disease, thymic hyperplasia with active germinal centers suggests that the breakdown in immune tolerance is initiated in the thymus, but the autoimmune reaction persists after thymectomy. Thymoma-associated myasthenia gravis is marked by a deficiency of the autoimmune regulatory protein AIRE, which appears to lead to a deficiency of regulatory T cells and a resultant increase in autoreactivity. Some autoreactive T cells may be activated in association with the thymoma because of local expression of muscle antigens, including the acetylcholine receptors, and the lack of AIRE. These autoreactive T cells can then stimulate peripheral B cells to



E-FIGURE 390-2. Effects of antibodies on the acetylcholine (ACh) receptor (AChR). In myasthenia gravis, complement-dependent lysis is likely to be the most important mechanism overall. Interestingly, there is no evidence of complement-dependent mechanisms in either the Lambert-Eaton myasthenic syndrome or acquired neuromyotonia, in which cross-linking of the respective ion channels with increased internalization seems to be the main mechanism. (Reproduced from Evoli A, Vincent A. Disorders of neuromuscular transmission. In: Goldman L, Schafer AI [Eds.]. *Goldman-Cecil Medicine*. Philadelphia: Elsevier; 2020:2509-2515.)

produce antibodies. Triggers for non–acetylcholine receptor antibody myasthenia gravis are not known. Patients with muscle-specific kinase antibodies have a normal-appearing thymus.

CLINICAL MANIFESTATIONS

Myasthenia gravis is characterized by fluctuating, painless muscle skeletal weakness, which can worsen over minutes to hours. Symptoms can vary across muscle groups and over time, with spontaneous remissions. This variability can lead to diagnostic challenges, especially when patients lack findings during clinical examinations. The majority of patients present with ocular muscle involvement that causes drooping eyelids or double vision (Fig. 390-1).[3] Ptosis may be unilateral or bilateral, and it often is asymmetrical. The pupils are always normal, an important finding that distinguishes myasthenia gravis from other ocular motility disorders and causes of ptosis, (e.g., third nerve palsy and Horner syndrome). Some patients have only isolated ocular muscle weakness (so-called ocular myasthenia), some patients have isolated weakness of bulbar muscles (which manifests as slurred speech, difficulty swallowing, and facial weakness), but the majority of patients will develop general weakness, especially in the proximal arms and legs and in respiratory muscles. Isolated bulbar weakness is particularly seen in patients who have muscle-specific kinase antibodies and who also may have muscle atrophy; these presentations can be confused with motor neuron disease (Chapter 387). Some patients have remarkably acute, lateralized weakness that mimics a stroke (Chapters 376 and 377) or distal weakness that may be confused with peripheral nerve injury (Chapter 388). Myasthenic crisis is defined as the need for ventilatory support for respiratory muscle weakness.[4]

Patients do not have sensory abnormalities, reflexes are normal, and bladder function is normal. Nevertheless, patients typically report a more substantial decrement in their quality of life than their physicians suspect.

DIAGNOSIS

Serologic testing is indicated when the clinical diagnosis of myasthenia gravis is suggested by ocular findings, especially when coupled with weakness or fatigue as documented by asking patients to maintain upgaze or hold their arms outstretched for 30 seconds to a minute. Provocative testing with edrophonium, ice packs, and rest tests should be performed only by individuals with extensive experience to avoid false positives.

Myasthenia gravis can be confirmed by serologic detection of acetylcholine receptor antibodies in about 50% of patients with isolated ocular myasthenia and upwards of 90% of patients with generalized disease. Muscle-specific kinase antibodies are present in about one-third of patients who do not have acetylcholine receptor antibodies, and very occasional patients may have both antibodies. False positives are exceedingly rare, but acetylcholine receptor antibodies can be detected in patients with thymoma and in asymptomatic family members of patients with myasthenia gravis. Low-density lipoprotein receptor–related protein 4 antibodies may be present in 1 to 4% of patients without other autoantibodies, but they are also detected in patients with motor neuron disease (Chapter 387).

In patients without serologic evidence of myasthenia gravis, electrodiagnostic studies can confirm a disorder of neuromuscular transmission. Approximately 75% of patients will have a decremental response to repetitive nerve stimulation. Single-fiber electromyography, which records action potentials generated by individual muscle fibers, has an estimated sensitivity over 95% when performed by experts (but is not likely to be that high in general practice).[5] However, single fiber examination is so sensitive that it will detect abnormalities produced by previous therapeutic botulinum toxin, thereby leading to the potential for a false positive evaluation. All patients should have chest imaging to detect a possible thymoma.

FIGURE 390-1. Marked ocular and facial muscle weakness in a young female with myasthenia gravis. (From Evoli A, Vincent A. Disorders of Neuromuscular Transmission. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.)

TREATMENT

If found on imaging, a thymoma should be removed. Postoperative radiation is recommended for completely resected stage II or III thymomas.[6] Unfortunately, this procedure does not eliminate the autoimmune disease and is not effective in reducing symptoms. For patients who do not have a thymoma, who are acetylcholine receptor antibody–positive, and who are younger than 65 years of age, thymectomy reduces weakness and the cumulative required medication dose over time.[A1,A2] Video-assisted thoracoscopic removal is as good as open surgery.[7] For patients who have muscle-specific kinase antibodies or do not have serum autoantibodies, thymectomy is not indicated.

For severe exacerbations of myasthenia gravis or myasthenia crisis, an immunoglobulin infusion (intravenous immunoglobulin [IVIG] 1 to 2 g/kg given over 2 to 5 days) or plasmapheresis can provide rapid improvement. The duration of response is usually only 4 to 6 weeks, so chronic therapy also must be instituted.

Consensus treatment guidelines[8] emphasize a trial of cholinesterase inhibitors (e.g., pyridostigmine [starting at 30 to 60 mg four times daily]) as first-line therapy to enhance neuromuscular transmission and reduce symptoms over the 3 to 4 hours after treatment. Unfortunately, cholinesterase inhibitors typically do not eliminate weakness, and they may cause gastrointestinal side-effects (bloating, nausea, and diarrhea) as well as increased respiratory secretions that can worsen reactive airway disease. Furthermore, they are much less effective in patients with muscle-specific kinase antibodies.

The most consistently effective treatment is high-dose prednisone (e.g., prednisone escalating to a maximum of 60 mg daily) that then should be tapered to the lowest effective dose, which may be maintained for years.[9] All patients have some adverse effects (Chapter 28), with 30% being severe, ranging from weight gain, diabetes, and hypertension to severe insomnia and osteoporosis. For the 20% or so of patients who do not respond to prednisone or have unacceptable adverse effects, immunosuppressive treatments[10] are warranted and can permit tapering of the prednisone dose.[A3] Rituximab (e.g., 375 mg/m^2 repeated weekly for 4 weeks) eliminates CD20 cells and appears to be effective for patients who have muscle-specific kinase antibodies, but its efficacy in patients with acetylcholine receptor antibodies is less clear.[11] Efgartigimod (an IgG1 antibody at 10 mg/kg as four weekly intravenous infusions, with a maximum dose of 1200 mg for patients who weigh more than 120 kg) is effective for generalized myasthenia gravis.[A4] Other immunosuppressive options include azathioprine (e.g., 2.5 mg/kg/day), mycophenolate (e.g., 2000 mg/day), tacrolimus (e.g., 3 mg/day), and less commonly methotrexate (e.g., 5 to 15 mg weekly). Each of these agents may require many months of therapy before they have biologic and clinical efficacy and may have significant toxicity. Intravenous eculizumab (e.g., 1200 mg every 2 weeks), which inhibits the activation of complement, is effective and well-tolerated in patients with acetylcholine receptor antibodies,[A5] but it is currently reserved for patients who have not responded to prednisone or immunosuppressive agents, in part because of its very high price. Other currently experimental immunotherapies[12] include zilucoplan (a complement inhibitor, given subcutaneously at 0.3 mg/kg daily for 2 weeks).[A6] The precise roles of these newer therapies continues to evolve, but these drugs do not eliminate the production of autoantibodies and, therefore, are unlikely to provide a continuous remission of weakness after they are discontinued. Experimental treatments include B cell ablation, cytokine inhibitors, and CAR-T cells.

Patients should be advised to be as physically active as possible once severe weakness is effectively treated. Exercise limits corticosteroids and may have further positive effects on the immune system.

PROGNOSIS

If not recognized and treated, myasthenic crisis will lead to death. There is no cure for myasthenia gravis. Effective therapies can eliminate symptoms in most patients, but more than 30% of patients have a poor response or intolerable adverse effects to first-line therapy. Patients suffer significant disability, with limitations in employment and compromised quality of life. With modern treatment, however, the lifespan of patients with myasthenia gravis is similar to that of the general population.

LAMBERT-EATON SYNDROME

PATHOBIOLOGY

Lambert-Eaton syndrome is caused by autoantibodies against the voltage-gated calcium channel on the presynaptic nerve terminal. The antibodies cross-link the calcium channels, thereby leading to increased internalization, which reduces the influx of calcium when the nerve terminal depolarizes and, as a result, reduces the vesicular release of acetylcholine. If the amount of acetylcholine is insufficient to activate the required number of acetylcholine receptors, no action potential will be generated to signal muscle contraction. If a nerve is repetitively stimulated during electrophysiologic testing, calcium will accumulate in the nerve terminal, can reach a level that is sufficient to overcome the defect, and will allow the release of acetylcholine. This accumulation is the basis of the incremental response observed in diagnostic testing, a response that is just the opposite of the fatigue seen with myasthenia gravis.

About 60% of patients with Lambert-Eaton syndrome have small cell lung cancer (Chapter 177), which expresses calcium channels that become the target of autoantibodies, whereas the remainder of patients have a primary autoimmune disorder. These latter patients tend to be younger, are more likely to be female, and often to have other autoimmune diseases. The specific stimulus that produces Lambert-Eaton syndrome in these patients is not known.

CLINICAL MANIFESTATIONS

Lambert-Eaton syndrome mimics myasthenia gravis in producing weakness and fatigue, but Lambert-Eaton syndrome tends to be characterized by more prominent proximal muscle involvement with comparatively limited ocular and bulbar muscle weakness. Patients often complain of proximal muscle aches, which are not common in myasthenia gravis.[13] Fluctuations in strength are often less obvious, and progressive weakness may be confused with a myopathy (Chapter 389). Autonomic disturbances, such as xerostomia, hypohydrosis, reduced lacrimation, constipation, and orthostasis, are common. In men, impotence and urinary retention also occur.

On examination, in addition to the expected weakness, pupillary reflexes may be slowed. Deep tendon reflexes are usually reduced but improve after exercise.

DIAGNOSIS

Serum antibodies to the voltage-gated calcium channel are detected in more than 95% of patients and are highly specific for Lambert-Eaton syndrome. On nerve stimulation testing, the compound muscle action potential may be reduced at baseline, which can lead to confusion with a motor neuropathy (Chapter 387), but rapid repetitive nerve stimulation or stimulation performed after brief exercise will lead to an incremental increase in the compound muscle action potential in about 90% of patients.

All patients must be screened for small cell lung cancer (Chapter 177) with a computed tomographic (CT) scan of the chest. If the CT scan is negative in a patient who smokes or is over age 40 years, fluorodeoxyglucose positron emission tomography (PET) scanning is recommended, with a CT scan every 6 months for up to 4 years. SOX1 antibodies are found in about two-thirds of patients with paraneoplastic Lambert-Eaton syndrome but are never positive in patients with the autoimmune form.

TREATMENT

For an acute crisis, plasmapheresis and IVIG (1 g/kg for 2 days) can provide improvement. First-line chronic treatment is with 3,4-diaminopyridine/amifampridine (10 to 20 mg four times daily, either in its base form or a phosphate version),[A7] which blocks potassium channels, prolongs the presynaptic potential, and increases the calcium concentration so that more acetylcholine is released from the nerve terminal.[14] The drug is contraindicated in patients with epilepsy. Paresthesias are common at the start of treatment. If patients do not respond well, pyridostigmine (60 mg three times daily and then increased as tolerated) should be added.

In patients with persistent symptoms, both the primary autoimmune and paraneoplastic forms of Lambert-Eaton syndrome should be treated with immunotherapy. Chemotherapy for small cell lung cancer (Chapter 177) or any other underlying tumor will often ameliorate the symptoms. Otherwise, options, as in myasthenia gravis, include prednisone, mycophenolate mofetil, azathioprine, and rituximab.

PROGNOSIS

Prognosis depends on the underlying condition.[15] For patients with the nonmalignant form, a normal lifespan can be expected but quality of life is reduced. With treatment, weakness can stabilize and gradually improve. For Lambert-Eaton syndrome associated with a malignancy, prognosis is dependent on the tumor's response to treatment.

CONGENITAL MYASTHENIC SYNDROMES

PATHOBIOLOGY

Congenital myasthenic syndromes are caused by rare genetic mutations of the presynaptic, synaptic, or postsynaptic machinery of neuromuscular transmission (see Table 390-1). Because these defects are not exclusive to the lower motor neuron, patients may have a broad range of neurologic manifestations in addition to abnormal neuromuscular transmission.

CLINICAL MANIFESTATIONS

Severe forms of congenital myasthenic syndromes typically present at birth with general weakness manifest with poor sucking and respiratory insufficiency. Progressive weakness and muscle atrophy can be confused with a primary myopathy. Mutations of presynaptic proteins and glycosylation defects can cause intellectual disability and seizures, which may mask identification of the neuromuscular transmission defect. In contrast to such severe forms, the slow channel syndrome and cholinesterase deficiency often are recognized in adulthood when patients develop fatigue, ocular findings, and progressive weakness.

DIAGNOSIS

Differentiation of congenital myasthenic syndromes from seronegative myasthenia gravis is critical so that ineffective immunosuppressive therapies can be avoided. The long history of progressive weakness in congenital myasthenic syndromes can help, but genetic analysis is the key diagnostic test and also guides drug therapy.[16]

TREATMENT

Treatment is guided by the genetic cause and should be managed at a specialized center.[17] Many patients will improve with pyridostigmine (60 mg three times daily and then increasing dose and frequency to maximal tolerated effect) as used for myasthenia gravis or with 3,4-diaminopyridine (250 mg/kg four times daily). Adrenergic receptor agonists, such as salbutamol (0.5 to 2 mg three times daily), improve several forms of congenital myasthenic syndromes, not only by an immediate effect but also over months to years. For the slow channel syndrome, open channel blockers such as fluoxetine (60 to 100 mg/day) normalize synaptic currents.

PROGNOSIS

Congenital myasthenic syndromes vary in severity from death in early childhood to mildly symptomatic disease with limited disability presenting in adulthood. Treatments may improve strength and limit disability.

NEUROMYOTONIA

DEFINITION AND EPIDEMIOLOGY

Neuromyotonia manifests as spontaneous muscle contractions from peripheral nerve hyperexcitability. Its prevalence is poorly defined, but it is even less common than Lambert-Eaton syndrome.

PATHOBIOLOGY

Voltage-gated potassium channels and an associated complex of proteins on the nerve surface are rapidly activated during the propagation of the motor nerve action potential. Antibodies primarily against the contactin-associated protein-2 (CASPR2) part of this system lead to repetitive discharges, which activate muscle.[18] These antibodies are acquired, often as part of a more generalized autoimmune disorder, but sometimes after infection, after an allergic reaction, or with a tumor (especially a thymoma or small cell lung cancer).[19] Mutations of the *HINT1* gene produce neuromyotonia with associated axonal neuropathy. Gene defects of calcium and potassium channels may also produce neuromyotonia.

CLINICAL MANIFESTATIONS

Beginning at any age, patients complain of irregularly undulating muscle movements, called myokymia, and stiffness, usually of limb muscles but also sometimes involving the face, tongue, and muscles of respiration. Fasciculations,

cramps, and pain are typical. The severity of neuromyotonia varies considerably from minor to profound disability.

On examination, typical findings include weakness; delayed muscle relaxation after voluntary contraction (pseudomyotonia), a positive Chvostek sign (contraction of the facial muscle with percussion in the area of the facial nerve), and a positive Trousseau sign (carpopedal spasm induced with restriction of blood flow, as with a blood pressure cuff). Muscular hypertrophy may be found in patients with long-standing disease. Sensory nerve involvement may lead to paresthesias and numbness. Constipation, tachycardia, and hyperhidrosis indicate involvement of the autonomic nervous system. Cognitive manifestations can range from personality alterations and insomnia to psychosis.

DIAGNOSIS

Confirmation of the clinical impression of muscular hyperexcitability is straightforward when electromyography shows characteristic spontaneous discharges, which are also present after contraction. Antibodies directed to voltage-gated potassium channels are found in the serum of some patients. Acquired neuromyotonia can be differentiated from genetic causes by a more abrupt onset and by the presence of autoantibodies. Genetic screening can be performed for known mutations.

TREATMENT

For autoimmune neuromyotonia, plasmapheresis or IVIG (as for myasthenia gravis) can provide short-term benefit for severe symptoms. Drugs that stabilize hyperexcitability, such as carbamazepine (up to 800 to 1000 mg daily), lamotrigine (up to 100 mg daily), or phenytoin (up to 300 mg daily), provide symptomatic relief. Immunotherapies, such as those used to treat myasthenia gravis, are sometimes useful. Treatment of any underlying malignancy may improve symptoms.

PROGNOSIS

Some patients have spontaneous resolution of symptoms, especially if the symptoms were precipitated by an infection. Most others respond to medications. For the paraneoplastic forms, prognosis depends on the underlying cancer.

BOTULISM

PATHOBIOLOGY

Clostridium botulinum (Chapter 271) and, rarely, other species of clostridium will produce toxin under anaerobic and acidic conditions. All strains of botulinum toxins are endopeptidases, which cleave proteins critical for synaptic vesicular fusion at cholinergic neuromuscular junctions and cholinergic synapses of the sympathetic and parasympathetic nerves.

CLINICAL MANIFESTATIONS

Foodborne botulism, which occurs with ingestion of a range of inappropriately home-processed foods and much more rarely commercially processed foods, including food in restaurants, can occur sporadically in an individual or as a cluster from a shared source. Wounds can be contaminated with *C. botulinum* in users of intravenous drugs but also may occur postoperatively.

Botulinum toxin can be aerosolized and used as a weapon or for bioterrorism (Chapter 19). Therapeutic administration of botulinum toxin for a wide range of disorders can have systemic adverse effects, particularly in patients who have preexisting disorders of neuromuscular transmission.

Symptoms of botulism typically begin with dysphagia, dysarthria, ptosis, and diplopia. Subsequent bilateral limb weakness and respiratory insufficiency can be fatal.[20] Weakness progresses over hours to days and is dependent on the amount of toxin. Additional autonomic features include constipation, diarrhea, and urinary retention. Gastrointestinal complaints, which include nausea and vomiting, should alert the clinician to the possibility of botulism because they are distinctly unusual in myasthenia gravis and Guillain-Barré syndrome (Chapter 388), which are the most common misdiagnoses. Absent pupillary reflexes, which also suggest botulism, never occur in myasthenia gravis and are exceedingly rare in Guillain-Barré syndrome.

DIAGNOSIS

Botulism can be confirmed by detection of the toxin by molecular testing (in serum, stool, or lavage fluid, or the food consumed by the patient) or culture of *Clostridium* species that produce the toxin from stool or wounds.[21] Repetitive nerve stimulation may demonstrate a defect of neuromuscular transmission, but normal findings do not exclude botulism, especially early in the course of the disease. In uncertain cases, neurophysiologic testing and analysis of the cerebrospinal fluid, (which is normal in botulism) can identify alternative diagnoses, such as the Guillain-Barré syndrome (Chapter 388) or myasthenia gravis.

TREATMENT AND PROGNOSIS

Outstanding critical care support is the most important determinant of outcome because affected individuals may require months of hospitalization for prolonged paralysis before the infection and toxin are cleared. Equine antiserum, which will not reverse weakness but can eliminate the toxin in circulation, should be instituted within 48 hours of the onset of suspected botulism and should not be delayed for confirmation of the diagnosis. Any wounds may be a source of infection and should undergo debridement. Specific antibiotic therapy is generally not recommended for botulism because antibiotics can lead to release of toxin.

The outcome of botulism depends on recognition and rapid institution of appropriate care, with about 50% of hospitalized cases resolving completely.[22]

OTHER NEUROTOXINS

Neurotoxins (see Table 390-1), which poison neuromuscular transmission, are produced by a variety of pharmaceutical agents, plants, and animals. Onset of weakness develops rapidly after exposure and may lead to death within minutes to hours. Recognition of such intoxication is usually straightforward if the encounter is with a snake or spider (Chapter 98), but is more challenging if a toxin, such as Novichok, is being used to poison an individual. The key to saving a patient is rapid institution of supportive care until the toxin is metabolized. In the case of tick bite, the exceedingly small tick, which is often found at the hairline, needs to be removed.

Organophosphate poisoning (Chapter 96) may occur with accidental exposure to a pesticide, intentional suicide, or intentional delivery in the form of a gas to produce widespread death or focused exposure to an individual by injection or inhalation. Patients will experience severe weakness in combination with manifestations of cholinergic excess: hypersalivation, pupillary constriction, diarrhea, and sweating. Treatment (see Table 96-3) is with atropine (1 to 2 mg, initial intravenous bolus, doubled every 5 minutes as needed and followed by a titrated infusion) and magnesium sulfate (4 g intravenously over 30 minutes).[23]

Many commonly used drugs may reduce the safety factor for neuromuscular transmission. This side-effect (Table 390-2) is not relevant in individuals with a normal neuromuscular junction but can have devasting consequences for patients who have an existing neuromuscular transmission disorder. Checkpoint inhibitors, now used widely in oncology (Chapters 164 and 166), can worsen

TABLE 390-2 DRUGS THAT WORSEN OR INDUCE NEUROMUSCULAR TRANSMISSION DISORDERS*

COMPROMISE SAFETY FACTOR	INDUCE AUTOIMMUNE REACTION
Aminoglycosides, macrolides	Penicillamine
Fluoroquinolones, clindamycin, telithromycin	Nivolumab, pembrolizumab, ipilimumab, tremelimumab, durvalumab
Hydroxychloroquine	
Procainamide, propranolol, propafenone	
Verapamil, quinidine	
Phenytoin, trimethadione, lithium	
Botulinum toxin	
Intravenous magnesium	

*This list is not exhaustive, and the clinician should consult myasthenia.org for a complete list of medications to use with caution in patients with disorders of neuromuscular transmission.

or even induce myasthenia gravis.[24] Penicillamine has long been known to induce myasthenia gravis by induction of an immune reaction, which often resolves with discontinuation of treatment.

391 DISEASES OF THE VISUAL SYSTEM

GEORGE A. CIOFFI AND JEFFREY M. LIEBMANN

The eye is a compact, complicated structure (Fig. 391-1) that is remarkably stable throughout life. Once the growth of the eye is complete, at approximately age 7 to 8 years, the structure of the eye changes very little throughout one's life.

The eyelids physically protect the eye. The pathway of light through the eye, termed the *visual axis*, ideally contains no opaque structures such as blood vessels. Light passes through the tear film, cornea, aqueous humor, crystalline lens, vitreous, and inner retina, all of which, except for the crystalline lens, remain essentially transparent throughout life. Delicate intraocular structures are protected by a tough collagenous "eye wall" composed of the cornea and sclera. The optic nerve, which is primarily composed of axons from the retinal ganglion cells, is enveloped by dura, arachnoid, and pia mater, which are contiguous with the dural layers of the brain. The myelination of the neural elements of the optic nerve begins at the posterior aspect of the eye. The orbital portion of the optic nerve is long enough to allow free excursions of the eye through a 100-degree arc under the influence of six coordinated and critically placed rectus muscles. All these functional components are housed in a bony cavity, the orbit, which protects the eye from external injury.

The eyelid skin, only loosely connected to underlying structures, is among the thinnest of the body. The eyelid is unique because it contains the highest density of sebaceous glands in the body. These meibomian glands produce a sebaceous (lipid) material that is the principal evaporation retardant for the tear film. Malorientation of the eyelid margin or malorientation of the lashes (trichiasis) may cause scarring of the anterior surface of the eye, even to the point of blindness, owing to diminished transparency of the cornea. The upper eyelid is opened by contraction of the levator muscle. The tendon of the levator tends to degenerate over time to produce mechanical ptosis ("drooping eyelids"). The soft tissue of the eyelid is separated from the soft tissue of the orbit by the orbital septum, a major collagenous barrier that protects intraorbital soft tissue from extension of preseptal eyelid inflammation and infection. Extension of inflammation from preseptal cellulitis or ethmoiditis may cause orbital cellulitis, thereby resulting in potential consequences such as cavernous sinus thrombosis. The elastic tissue supporting the skin of the anterior eyelid is reduced over time, thereby causing dermatochalasis ("baggy eyelids"). Redundant tissue of the superior eyelid may be sufficient in quantity to restrict the visual field.

The conjunctiva is a mucous membrane with an outer layer of stratified, nonkeratinizing squamous epithelium containing goblet cells. The epithelium is supported by delicate fibrovascular tissue that contains lymphatic channels. The conjunctival epithelium also contains melanocytes. Squamous carcinoma or malignant melanoma originating in the conjunctiva may extend through these channels to regional lymph nodes or beyond. Immune processing cells are present in the epithelium (Langerhans cells) and in the stroma as collections of non-nodal B and T lymphocytes. Non-nodal primary lymphomas, which tend to have an indolent course in this location, may arise from this tissue. The aqueous portion of tears is formed constantly by accessory lacrimal glands in the conjunctiva as well as by reflex action from the lacrimal gland. Symptoms of itching and burning, as well as periodic disturbance of vision, may result from inadequacies of the tear film layer.

Tears drain through two puncta located at the nasal eyelid margin (one in the upper lid and one in the lower lid) into the nasolacrimal duct, which exits into the nasal cavity under the inferior turbinate. The epithelium of the nasolacrimal duct also contains melanocytes and is supported by a resting lymphocyte population. Neoplasms including lymphoma, concretions (dacryoliths), and tissue injury from trauma may occlude the puncta and nasolacrimal system in adults.

The cornea is avascular and lined anteriorly by epithelial cells and posteriorly by endothelial cells. Lack of an adequate tear film (dry eye syndrome) may seriously alter the ability of the cornea to transmit light, thereby affecting visual acuity. The posterior cellular lining of the cornea is a single layer of highly modified corneal endothelial cells that maintain tissue dehydration. Lack of effective pumping by the endothelial cells will allow excess hydration of the corneal stroma—that is, corneal edema—which diminishes the transmission of light. The corneal stroma is particularly sensitive to proteolysis from collagenases found with certain inflammatory conditions, such as herpes simplex and zoster keratitis. The cumulative effect of multiple episodes of corneal inflammation may be thinning and even perforation of the cornea or, alternatively, thickening and scarring.

The anterior chamber is bounded by the posterior surface of the cornea, the anterior surface of the iris, and the anterior surface of the crystalline lens within the pupillary space. The posterior chamber is bounded by the posterior surface of the iris, the ciliary body circumferentially, and the anterior surface of the vitreous. Aqueous humor normally flows from the posterior chamber into the anterior chamber through the pupil and exits into the general circulation through the trabecular meshwork and a series of collector veins. Most causes of pathologically increased intraocular pressure and optic nerve damage (e.g., glaucoma) are due to abnormalities of filtration through the trabecular meshwork. The crystalline lens is located entirely in the posterior chamber.

The anterior segment is composed of the cornea and the anterior and posterior chambers. Most of the anterior segment is derived from the skin and neural crest tissue. The posterior segment is the remainder of the eye. Most of the posterior segment structures are derived from the central nervous system and neural crest tissue.

When first formed, the crystalline lens is a totally cellular structure bounded by a true basement membrane. Throughout life, the new cells that are continuously added from the outer-layer epithelial cells compress the central cells, thereby resulting in cell degeneration in the central core (nucleus). The lens doubles in volume from birth to age 70 years at the cost of both pliability (presbyopia) and clarity (cataract). The lens is suspended in the posterior chamber by fibers (zonules) attached to the ciliary body.

The ciliary body comprises the middle layer of the eye wall, the uveal tract. The uveal tract extends under the retina as a vascular plexus, the choroid, and the iris. The surface cells of the ciliary body produce aqueous humor, and its muscles function in accommodation.

The vitreous is composed primarily of water and type II collagen. The vitreous makes up the majority of the volume and weight of the eye. It functions as a biochemical sink as well as to maintain neural retinal attachment. With time, the vitreous shrinks and separates from the retina (posterior vitreous detachment). Condensed vitreous opacities, which cast shadows on the retina, are perceived by the patient as "floaters."

The retina is the site of photochemical conversion of light to electrical energy. Ganglion cells and their axons in the internal retina aggregate at the optic disc to form the optic nerve. Only the inner half of the retina is supplied by intraretinal vessels that are seen by ophthalmoscopy. The outer half of the retina is supplied by large-caliber capillary vessels in the choroid (the choriocapillaris). Extensive biochemical support and control of stray light are performed by the retinal pigment epithelium located between the choriocapillaris and the photoreceptor outer segments. The density of photoreceptor cells (rods and cones) varies across the retina. Only a 500-μm area of the posterior retina, the central macula (about 3 to 5% of the total retina), has a high enough density of photoreceptor cells, primarily cones, to allow images to be resolved to 20/20. The remainder of the retina has much less sensitive image resolution owing to a lower density of photoreceptor cells. The blood-retinal barrier, which protects the biochemical integrity of the retina, is composed of anatomic attachments between neighboring retinal pigment epithelial cells, as well as attachments between vascular endothelial cells of the retinal circulation. The retina is held in place by physiologic forces that may be compromised by holes in the retina (rhegmatogenous retinal detachment) or by fluid accumulating in the subretinal space without a retinal hole (nonrhegmatogenous retinal detachment).

The optic nerve is composed of approximately 1 million axons from retinal ganglion cells. Axons are separated into bundles by pial septa, which are in turn enclosed in an arachnoid layer. The dura is contiguous with the posterior sclera and the periosteum of the optic canal. Delicate vessels extending from the dura across the arachnoid to the pial septa supply the optic nerve. The central retinal artery is present in the axial layer of the optic nerve near the eye but does not supply blood to the optic nerve itself. The optic nerve axons travel through a collagenous sieve in the plane of the posterior sclera, the lamina cribrosa. The choroid is that portion of the uveal tract external to the retina. This layer is composed of various calibers of blood vessels that ultimately supply blood for the choriocapillaris.

The sclera is composed of dense, relatively disorganized collagen. It is opaque because of the nonhomogeneous structure of the collagen and the degree of hydration relative to the cornea. There are multiple scleral ostia for the passage of arteries, veins, and nerves, both posteriorly and anteriorly.

ABSTRACT

The structure and function of the eye is affected by normal aging and local and systemic diseases. Although the detection of the loss of vision and disease screening typically require use of specialized equipment and personnel, the eye examination may reveal neurologic, cardiovascular, endocrinologic, and inflammatory disease that aids in systemic disease diagnosis and management across all fields of medicine.

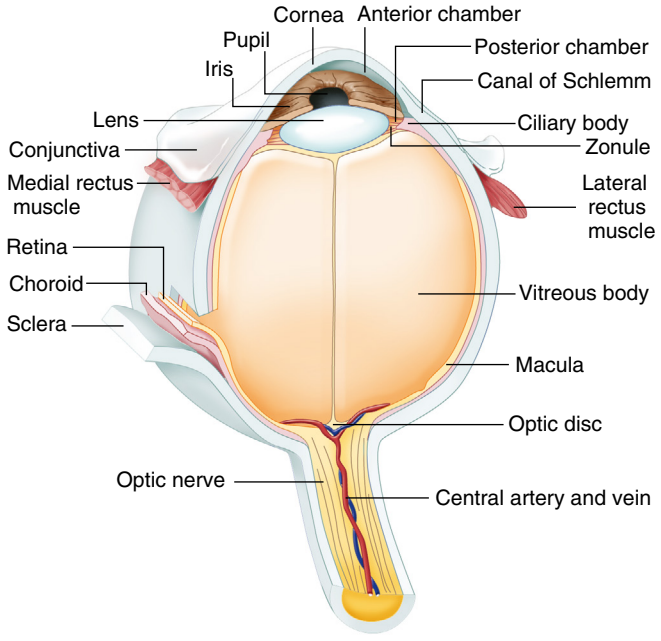

FIGURE 391-1. **Anatomy of the eye.**

The orbit is composed of bones of the facial skeleton. Sutures between major bones exist in the superior nasal and superior temporal quadrants. Multiple vessels and nerves extend through the thin ethmoid bone from nasal sinus tissue medially. The orbital floor, which is a relatively thin layer of bony support over the maxillary sinus, may rupture with increased intraorbital pressure or after blunt trauma to the inferior orbital rim. The nasolacrimal duct travels through a portion of the lacrimal bone. Portions of the sphenoid bone protect the optic nerve. Major cranial nerves travel through the adjacent superior orbital fissure, also a portion of the sphenoid bone. There is no normal lymphoid tissue in the orbit outside of the lacrimal gland. The rectus muscles may be enlarged by inflammation in thyroid eye disease, but the tendinous insertion into the sclera is usually not inflamed early in the course of the disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients may present with complaints of diminished vision, eye pain, redness, or pain around the eye. The causes may be primarily ophthalmic (e.g., cataract) or systemic (e.g., diabetic retinopathy). A comprehensive ophthalmologic examination also should evaluate for possible asymptomatic local (e.g., choroidal melanoma) or systemic (e.g., hypertensive retinopathy) abnormalities in patients with normal acuity and no subjective complaints.

Functional Evaluation

The most objective and common measure of ocular function is line letter acuity, with normal vision (Table 391-1) defined as the ability to see at 20 feet what a normal person sees at 20 feet, known as 20/20 vision (E-Fig. 391-1). Less than 20/20 vision can be caused by an abnormality anywhere from the tear film to the visual cortex of the occipital lobe (see Fig. 391-1). However, normal vision also includes other functions, such as the perception of color, motion, contrast, brightness, field, and depth, for which there is greater variation among individuals. Normal visual acuity is potentially achievable in essentially all individuals, either naturally or with the correction of the refractive error. Although effective treatments are available for refractive errors, cataracts, glaucoma, and other eye conditions, there is no evidence that routine screening for impaired visual acuity is associated with improved clinical outcomes.[A1]

Correction of vision is based on the refraction of light (Fig. 391-2). The diopter (D) is the unit of measurement of the ability of an optical system to refract (bend) light. The normal human eye has a refractive capacity of approximately 60 D, which is accomplished by the cornea and the crystalline lens. This refractive capacity is needed to focus light onto the central retina, the macula. If the eye is too short, light will be focused behind the eye (hyperopia). If the eye is too long, light will be focused in the vitreous cavity in front of the retina (myopia). Normally, a person can involuntarily control the crystalline lens, alternating between near and distant tasks. During the fourth and fifth decades of life, the lens becomes less pliable and the eye loses its ability to alter its shape (presbyopia). Refraction is the method of determining the amount of optical correction (strength of glasses) needed to establish 20/20 vision.

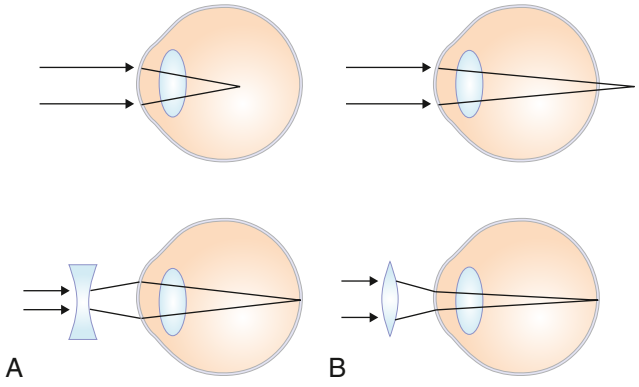

FIGURE 391-2. **Myopia/hyperopia. A,** In the myopic eye, parallel rays of light are focused anterior to the retina. A divergent lens can be used to compensate for the mismatch between refracting power and axial length. **B,** The hyperopic eye requires the additional power of a convergent lens to bring images into focus on the retina.

Examination of pupillary response assesses whether neural function is intact (see Figs. 392-2 and 392-4). Confrontational visual field testing (see Fig. 392-1 in Chapter 392) should be performed in each eye to detect gross quadrantic defects. Extraocular motility should be assessed to exclude nerve or muscle abnormalities (see Table 392-6). Color vision testing plates are a sensitive indicator of optic nerve function and for detecting genetic variations that result in deficiencies of color perception.

Diagnostic testing during a routine eye examination also includes external examination of the lids and adnexa, applanation tonometry to determine intraocular pressure, biomicroscopy (slit lamp examination) of the anterior segment, and ophthalmoscopic examination of the ocular fundus (the retina and associated structures). Other tests include exophthalmometry (measurement of proptosis), visual field and electrophysiologic testing and imaging (fluorescein angiography, mainly in diabetic patients; optical coherence tomography [OCT] to investigate retinal disease and glaucomatous damage), and corneal topography.

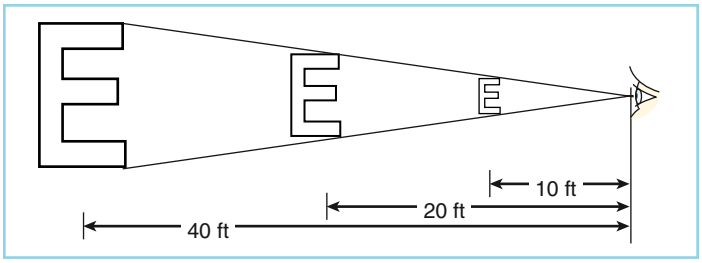
The conjunctiva, cornea, lens, and anterior chamber are evaluated using a slit lamp biomicroscope. The slit lamp is composed of a binocular microscope with variable magnification (40× and 80×) in conjunction with adjustable light sources. An increased concentration of protein can be detected in the anterior chamber because of the Tyndall (flare) effect, indicating vascular incompetence associated with either inflammation or ischemia. Even individual inflammatory cells can be resolved with the slit lamp. A cobalt blue filter can be used to detect fluorescein dye that accumulates in regions of abnormal epithelium (dendrite of herpes simplex keratitis or a corneal abrasion). The slit beam is used to examine the crystalline lens to determine the depth of the anterior chamber and the degree of opacification from a cataract. By using a green filter with the 90-D lens, the retinal vessels and retinal vascular abnormalities such as microaneurysm can be seen.

COMMON CLINICAL CONDITIONS

Chronic Abnormal Vision

MYOPIA

Nearsightedness (myopia; see Fig. 391-2) is usually discovered during childhood when children cannot perform distant tasks during school (reading the



E-FIGURE 391-1. Snellen visual acuity. The most common test for visual acuity measures the eye's ability to resolve linear images at a test distance of 20 feet, approximating infinity (parallel rays of light). A 20/20 E subtends 5 minutes of arc at a distance of 20 feet, with each segment of the E subtending 1 minute of arc. The larger letters (e.g., 20/30, 20/40) are determined by the distance at which they subtend an angle of 5 minutes. Thus, an E that subtends 5 minutes at 40 feet, if viewed clearly at 20 feet, indicates 20/40 visual acuity.

blackboard) or during school screening. Myopia usually progresses until age 20 to 25 years. Rapidly progressing myopia at any time after age 25 years requires evaluation for diabetes mellitus (reversible metabolic changes in the crystalline lens), trauma (development of a cataract), or use of corticosteroids (development of a cataract). Nonpathologic forms of myopia are usually fully correctable with eye glasses or contact lenses or can be corrected to a visual acuity of 20/40 or better in 95% or more of patients by various forms of laser-assisted in situ keratomileusis (LASIK).[A2] Complications of LASIK include glare symptoms, dry eye, and undercorrection or overcorrection.[1] Rare but serious complications include epithelial ingrowth, diffuse keratitis, and flap dislocation.

Pathologic myopia is a partly heritable condition causing progressive weakening of the posterior sclera and resulting increases in the axial length of the eye. Localized areas of deformation arise where there is an abrupt increase in the posterior radius of curvature of the eye (posterior staphyloma). The axial length of a normal eye is typically between 20 and 24 mm, whereas it can increase to above 25 mm in pathologic myopia and may be as high as 40 mm in severe cases. Abnormal physical forces in pathologic myopia may lead to retinal hole formation, retinal detachment, choroidal neovascularization, or intraocular hemorrhage. Associated systemic conditions include Cornelia de Lange syndrome, Stickler syndrome, and Marfan syndrome. Clinical surveillance is important to identify treatable complications such as retinal holes and detachment. Pathologic myopia is treated palliatively with eye glasses or contact lenses. Refractive procedures are less successful in pathologic myopia because of the severity of the refractive errors and the presence of posterior segment abnormalities. Surgical and laser procedures may be required to treat retinal and choroidal lesions.

HYPEROPIA

In hyperopia (farsightedness; see Fig. 391-2), in contrast to myopia, the eye tends to have a shorter than average axial length. Shorter axial lengths are associated with narrow-angle glaucoma and angle-closure glaucoma. Compensatory mechanisms of the crystalline lens may functionally correct small degrees of hyperopia until age 40 years, when the crystalline lens loses its pliability. The initial pair of glasses may have to correct for both distance and near tasks (bifocals). Refractive surgical procedures can correct up to 5 D of hyperopia.

PRESBYOPIA

Presbyopia typically presents in the fourth to sixth decades of life and manifests as a progressive decrease in the ability to focus clearly on near objects. Presbyopia results when the crystalline lens loses its pliability, thereby preventing light rays from close objects from focusing onto the retina. The lens is suspended by fibers (zonules) attached to the ciliary body. In youth, the musculature of the ciliary body, acting via the zonules, alters the shape of the lens to provide increased near focusing power. As the lens hardens and presbyopia ensues, symptoms include difficulty reading small print, eyestrain, headaches, and the inability to read material unless it is farther away. Treatment is typically with eye glasses, such as bifocals, to provide adequate magnification to replace the lost ability of the eye.

ASTIGMATISM

Astigmatism derives from changes in the radius of curvature of the cornea and from the lens. Symptoms are predominantly blurry vision with "shadowing" and difficulty seeing fine detail. Regular astigmatism is not a pathologic state but rather a variation in anatomy; most people have some degree of regular astigmatism that can be corrected with eye glasses or contact lenses. Irregular astigmatism is usually from changes on the cornea (e.g., from scarring owing to infections or trauma) or from adjacent tissue on the cornea (e.g., pterygia or limbal masses that induce changes in the corneal curvature). Some forms of regular astigmatism can be corrected with corneal laser ablation, but irregular astigmatism often requires correction with rigid contact lenses.

KERATOCONUS

Keratoconus is an acquired thinning of the cornea that induces irregularities of the corneal surface and irregular astigmatism; its cause is controversial but probably is partly genetic. Chronic eye rubbing has been associated with progressive disease. Onset generally is during adolescence, and the process often evolves over 5 to 10 years. The prevalence in the United States is approximately 55 cases per 100,000, but this figure may underestimate subclinical cases. Corneal surface mapping allows earlier and more precise diagnosis.

Patients with keratoconus typically report a progressive worsening of vision, sometimes severe. The condition is usually bilateral but not symmetrical. Mild degrees of early keratoconus can be corrected with glasses or contact lenses. The condition is typically progressive, but corneal collagen cross-linking can halt the progression in early to moderate cases and provide a sustained improvement in vision. For severe cases with significant corneal scarring and intolerance to contact lenses, corneal transplantation (graft) is the primary therapy.

STRABISMUS

The control of simultaneous orientation of the two eyes to ensure that the visual axes of both eyes are aligned is not complete until 6 to 12 months following birth. Misalignments of the two eyes (strabismus) may be the result of abnormalities in the central oculomotor nuclei of the brain, malfunction of one or several oculomotor nerves, or intrinsic abnormalities of the rectus or oblique muscles (see Fig. 392-6). If the eyes are not simultaneously stimulated with the images of the same degree of clarity or complexity, there is a risk that only one eye will develop normal vision (amblyopia). In most cases, only the central vision is affected, so the peripheral vision in both eyes is likely to be normal. Binocular vision can be disrupted with amblyopia, with a loss in depth perception that may become permanent if the normal eye alignment is not restored.

Amblyopia also may be caused by a marked difference in refractive error between the two eyes (anisometropic amblyopia), congenital cataracts, or eyelid ptosis (deprivational amblyopia). Ptosis may be neurogenic or mechanical (e.g., congenital eyelid hemangioma). To avoid amblyopia, it is extremely important to refer a child with strabismus to an ophthalmologist as soon as the strabismus is noted.

Treatment options include patching or atropine eye-drops (1%, typically daily but effective if used as infrequently as twice per week) to blur the better-seeing eye, thereby strengthening the amblyopic eye. These therapies have been shown to be equally effective in providing good vision if patients are treated before age 7 years. The outcome of treatment is more favorable if amblyopia is detected before age 2 to 3 years but may be occasionally successful into the teenage years depending on the severity. Success is directly related to compliance and the timeliness of diagnosis.

Esotropia is a deviation of one eye inward ("crossed eyes"). Although intermittent esotropia may be a normal finding in infancy, it should not be present beyond 6 months of age. Delay in facial maturation (underdeveloped nasal bridge) may give the appearance of esotropia, even though the visual axes are correctly aligned. In true strabismus, the corneal light reflex will be in the center of one cornea and decentered in the other.

Exotropia is deviation of one eye outward. Exotropia is often intermittent and less likely to result in amblyopia compared to esotropia. Like esotropia, intermittent exotropia may also be a normal developmental finding in infancy.

In some cases, esotropia or exotropia may be treated by using appropriate corrections of refractive error with glasses (occasionally bifocals). It is critically important to recognize that strabismus may be the presenting sign of vision loss due to other causes (e.g., retinoblastoma). Extraocular muscle surgery may be necessary to correct alignment.

DIPLOPIA (DOUBLE VISION)

Acute onset of diplopia is an ominous sign suggestive of a cranial nerve palsy (i.e., III, IV, or VI) or pathology in the orbit (Chapter 392). Diplopia of any kind is usually an intolerable symptom, which is often worse with vertical deviations than horizontal deviations.

COLOR VISION CHANGE

Most cases of congenital color blindness are genetically determined and go undetected for many years. Acquired color deficiency at any age may be caused by a cataract or optic nerve disease.

CHANGE IN VISION

If only one eye has a change in vision, the problem, such as a cataract or retinal detachment, is most likely in that eye. If both eyes have a change in vision, the problem generally is outside of the eye, such as homonymous hemianopia (Chapter 392). Improvement of near vision in middle age may be a sign of cataract ("second sight") or hyperglycemia. Transient complete or partial unilateral or bilateral loss of vision may be caused by vascular abnormalities inside or outside of the eye (Table 391-2).

ACUTE EYE ABNORMALITIES

PAIN

The most severe eye pain (Table 391-3), typically associated with a red eye, is caused by acute angle-closure glaucoma. Sharp, intermittent pain is usually

caused by ocular surface abnormalities (e.g., corneal foreign body). Burning pain that clears with blinking generally relates to tear film abnormalities (dry eyes). Deep boring pain most often is associated with an ocular abnormality (e.g., uveitis).

RED EYE

A red or inflamed eye can be caused by conjunctivitis (allergic, inflammatory, or infectious), iritis (anterior uveitis), acute glaucoma, ocular trauma, or infection (Table 391-4).[2] All of these causes are typically painful to varying degrees.

DISTORTED VISION

Distorted vision (metamorphopsia), which is the perception that straight lines are distorted or bowed, results from macular dysfunction. Causes include fluid under the retina; macular degeneration, which tends to elevate the retina; and an epiretinal membrane, which tends to contract the retina.

NIGHT BLINDNESS

Retinitis pigmentosa, vitamin A deficiency, and systemic medications such as phenothiazines can cause true night blindness, in which patients have difficulty seeing any stars in the sky on a clear night and may be unable to ambulate without assistance in a dark environment. Patients with cataracts may have difficulty driving at night because of excessive glare and visual distortion. Gene therapy using adeno-associated virus vectors carrying the *RPE65* gene has been shown to increase retinal sensitivity and to improve night vision in patients with retinitis pigmentosa.

Dry eyes	Scleritis
Ectropion	Trauma
Entropion	Uveitis
Foreign object	

SENSATION OF FLASHING LIGHTS

The sudden onset of flashes (photopsia) in the peripheral visual field suggests traction of the vitreous on the peripheral retina, sometimes with a resulting retinal tear. The flashes, which may be more pronounced in the dark and with rapid eye movement, may be associated with the sudden onset of floaters, which can indicate debris or blood in the vitreous cavity. Because a tear in the retina can lead to a retinal detachment, urgent consultation with an ophthalmologist is required.

Flashing light with a migraine (Chapter 367) is described as scintillations or zigzagging lights that march across the visual field for a few minutes or as long as 30 minutes, sometimes associated with transient visual field loss. Headache is not universal.

FLOATERS

Floaters, which are caused by small aggregates or opacities in the vitreous cavity, result from the normal aging of the vitreous. The acute onset of vitreous floaters may be associated with uveitis or with the sudden onset of bleeding in the vitreous cavity owing to diabetes or vascular occlusions. Acute floaters, however, particularly if associated with flashing lights, may indicate a posterior vitreous detachment and/or a retinal tear with an impending retinal detachment. Urgent ophthalmic referral is essential.

PHOTOPHOBIA

Photophobia, particularly if associated with eye pain, redness, and decreased vision, is a symptom of intraocular inflammation (uveitis) from trauma or other causes. Photophobia is also typical of acute migraine and meningeal irritation. Prompt ophthalmologic referral is prudent.

HALOS AROUND LIGHTS

Patients with cataracts commonly see halos around lights, particularly when driving at night. Episodic decreased vision, redness, and halos around lights may be symptoms of impending angle-closure glaucoma owing to increased intraocular pressure with resulting corneal edema and loss of corneal clarity. Halos also can occur as a complication of refractive eye surgery.

FOREIGN BODY SENSATION

A foreign body sensation is commonly caused by ocular surface diseases such as dry eye syndrome (see later). Entropion (see Fig. 391-3) or misdirected lashes (trichiasis) also can cause a foreign body sensation. Most corneal abrasions cause severe pain, but minor corneal abrasions may be associated with a foreign body sensation rather than the severe pain. An arc welder burn causes a punctate corneal keratopathy, and foreign body sensation may be a prominent symptom. A true conjunctival or corneal foreign body also may be present.

EXCESSIVE TEARING (EPIPHORA)

Tearing can occur because of the overproduction of tears or impairment of tear drainage. Any abnormalities in upper or lower lid laxity, position, or closure can impair the lacrimal pump system. The most common cause of epiphora is

TABLE 391-4 DIFFERENTIAL DIAGNOSIS OF COMMON CAUSES OF INFLAMED EYE*

FEATURE	ACUTE CONJUNCTIVITIS	ACUTE IRITIS†	ACUTE GLAUCOMA‡	CORNEAL TRAUMA OR INFECTION
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Slightly blurred	Markedly blurred	Usually blurred
Pain	None	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse: more toward fornices	Mainly circumcorneal	Mainly circumcorneal	Mainly circumcorneal
Cornea	Clear	Usually clear	Steamy	Change in clarity related to cause
Pupil size	Normal	Normal or small	Moderately dilated and fixed	Normal or small
Pupillary light response	Normal	Normal or reduced	None	Normal
Intraocular pressure	Normal	Variable	Elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal ulcers related to infection

*Less common causes of red eyes include endophthalmitis, foreign body, episcleritis, and scleritis.
†Acute anterior uveitis.
‡Angle-closure glaucoma.

chronic or acute irritation that results in the overproduction of reflex tearing from ocular dryness (dry eye syndrome). Ocular surface irritants, such as trichiatic eyelashes touching the cornea, also can stimulate excessive tear production. Obstruction of the nasolacrimal tear drainage system owing to age, inflammation, infection, trauma, or neoplasm can prevent appropriate tear drainage. Treatment depends on the underlying condition.

EYELID TWITCHING

Any irritation of the conjunctiva or cornea can cause the eyelids to twitch. Occasional twitching of the lids usually is associated with stress or adrenergic stimulation. Benign essential blepharospasm is severe spasm of the lids leading to functional impairment. Multiple sclerosis (Chapter 380) also can cause lid spasm.

CONJUNCTIVITIS

Any ocular inflammation, including corneal ulcers, angle-closure glaucoma, endophthalmitis, and uveitis, can be associated with secondary conjunctival hyperemia. Conjunctivitis usually involves the entire conjunctiva, is associated with a discharge, and may or may not be associated with pain (see Table 391-4).

PTOSIS (DROOPY EYELID)

Ptosis (Fig. 391-4) is typically due to age-related degeneration and even disinsertion of the levator palpebrae superioris muscle. However, it also can be caused by a third nerve palsy, Horner syndrome, myasthenia gravis (Chapter 390), or other neurologic conditions. Third nerve palsy is usually associated with diplopia and a large pupil. Horner syndrome (see Fig. 392-5) is associated with a small pupil and ipsilateral anhydrosis. With myasthenia gravis (Chapter 390), other typical features of muscle weakness and fatigability are usually present or can be elicited. Non-neurologic causes of ptosis include age-related dehiscence of the levator muscle.

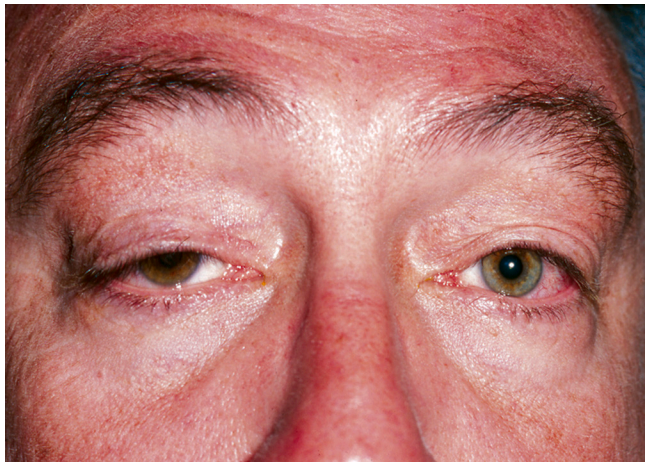

FIGURE 391-4. Ptosis of the right upper lid. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology*, 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

PROPTOSIS (EXOPHTHALMOS)

Proptosis, or a prominent globe, can be a manifestation of thyroid eye disease, which in turn is associated with thyroid abnormalities, especially Graves disease (Chapter 207). In this setting, proptosis can be subacute and asymmetrical. Any orbital inflammation, infection, or neoplasm can cause unilateral proptosis; in the case of inflammation or infection, proptosis is typically acute in onset. All orbital processes can affect orbital cranial nerves, with associated diplopia or optic neuropathy. Orbital infection, or cellulitis, typically presents with concurrent severe eye redness, pain, sinusitis, and an elevated white blood cell count (Fig. 391-5). Idiopathic orbital inflammation can cause acute, usually unilateral proptosis, with severe pain, particularly with eye movement, and often with decreased vision. An optic nerve tumor causes chronic, unilateral proptosis associated with a slow onset of visual field loss. Acute cellulitis can be associated with unilateral proptosis, severe redness, and moderate to severe pain, commonly with sinusitis and an elevated white blood cell count.

SMALL PUPIL

A unilateral small pupil is best detected in dark conditions. Causes include Horner syndrome, associated with ptosis on the same side; the bilaterally small, poorly reacting pupils of tertiary syphilis (Argyll Robertson pupils), which accommodate with normal constriction to a near object; miotic drops (e.g., pilocarpine); traumatic iritis; uveitis; and opioids.

LARGE PUPIL

Any α-adrenergic or anticholinergic agent placed into the eye can cause a large pupil. With eye trauma, the iris sphincter muscle can be damaged, and an abnormally large pupil can result. Tears in the iris sphincter can sometimes be appreciated on slit lamp examination. Third nerve palsy may cause a dilated pupil associated with ptosis and decreased elevation, depression, and medial eye movement. Adie pupil (see Fig. 396-3) is an idiopathic, unilateral large pupil that is hypersensitive to weak cholinergic stimulation. Recent eye surgery with pharmacologic dilation, uveitis, an acute angle-closure glaucoma attack, and traumatic iritis can cause a large pupil.

LEUKOCORIA

Leukocoria (white pupil) in a young child is critically important, because it may be a sign of retinoblastoma. Some of the more common non-retinoblastoma conditions presenting with leukocoria (Table 391-5) include cataracts, retinal detachment, persistent fetal vasculature (a developmental anomaly of the vitreous resulting in intraocular fibrosis and retinal detachment), Coats disease (a developmental vascular malformation of the retina leading to exudative retinal detachment), and ocular toxocariasis (a parasitic intraocular nematode infection that leads to intraocular scarring and retinal detachment).

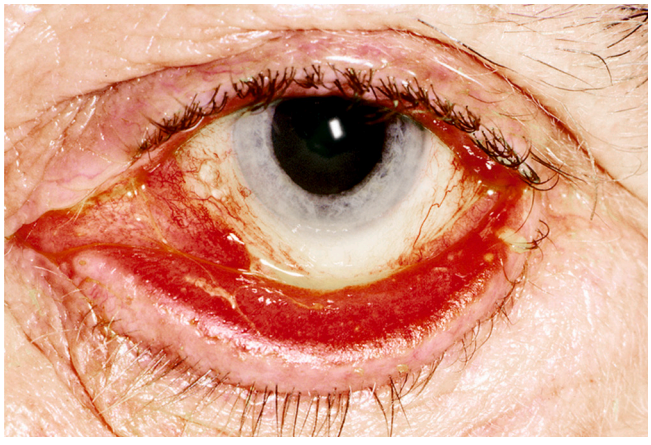

FIGURE 391-6. Involutional ectropion. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology*, 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

EYELID ABNORMALITIES

ECTROPION AND ENTROPION

An ectropion is an out-turning of the eyelid, typically the lower lid (Fig. 391-6), with exposure of the undersurface of the lid. Causes include aging, scarring, a mass on the eyelid, and seventh nerve (Bell) palsy. Common symptoms, which derive from corneal exposure and drying, include burning, itching, tearing, and the sense of a foreign body. Treatment is surgical, although mild symptoms may be managed conservatively with lubrication.

An entropion, which is an in-turning of the eyelid (see Fig. 391-3), is usually age related and associated with irritation, burning, and a foreign body sensation because the eyelashes touch the cornea. If it leads to trichiasis, in which the eyelashes rub or abrade the cornea, the lashes can be removed with forceps or surgery to correct the eyelid malposition. Botulinum toxin can be injected into the orbicularis muscle to temporarily correct the entropion.

CHALAZION

A chalazion (Fig. 391-7) is a localized lipogranulomatous inflammation owing to an occluded sebaceous (meibomian) gland. The retained, lipid-rich sebaceous material acts as a foreign material that stimulates a lipogranulomatous foreign body inflammatory reaction. A painless or slightly tender, nonmobile nodule forms under the eyelid skin. Most lesions resolve over days to weeks with warm compresses or without specific treatment. If the chalazion persists, it may be surgically débrided. Some individuals may have recurrent chalazia. A recurrent chalazion in the same spot may point to an underlying carcinoma.

HORDEOLUM (STYE)

A hordeolum (stye) (Fig. 391-8) is a painful abscess in a hair or eyelash follicle or in a sebaceous gland. Styes are usually self-limited infections that respond to warm compresses and topical antibiotics (e.g., bacitracin or erythromycin ointment or moxifloxacin or gatifloxacin drops). An ophthalmologist may perform incision and drainage if symptoms do not improve within 48 hours.

BLEPHARITIS

Blepharitis (Fig. 391-9) is a common, nonspecific inflammation of the eyelid margin or skin. The condition is usually bilateral and symmetrical. Rosacea (Chapter 406) is the most common associated cutaneous condition, and *Staphylococcus aureus* is the most common infectious agent. If untreated, blepharitis becomes chronic and may lead to corneal and conjunctival inflammation (blepharoconjunctivitis). Effective supportive care for blepharitis includes warm compresses and maintenance of good lid hygiene. Ophthalmic antibiotic ointment (e.g., bacitracin or erythromycin) is more efficacious than eye-drops, but systemic antibiotics (e.g., minocycline, 50 to 100 mg; doxycycline, 100 mg, once daily; tetracycline, 250 mg twice daily; or erythromycin, 250 mg three

FIGURE 391-7. Bilateral chalazion in the upper eyelids.

times daily) infrequently may be recommended, particularly if there is any evidence of inflammation of the cornea or conjunctiva.

In seborrheic blepharitis, exfoliated keratinous debris accumulates along the eyelid margin, particularly at the follicles of the eyelashes, and irritates the conjunctiva. Treatment of this chronic condition is directed at mechanically removing the keratinous debris by scrubbing the eyelid and eyelashes daily with a mild detergent ("baby shampoo") in warm water applied with a soft cloth.

BENIGN EYELID NEOPLASMS

Skin tags, also known as acrochordons, are the most common benign skin lesions of the lids and periocular region. Other skin lesions include seborrheic keratitis, actinic keratitis, inverted follicular keratitis, papillomas, and benign lesions of the eccrine and apocrine systems. Most of these benign lesions are cured by simple excision.

SEBACEOUS CARCINOMA

Sebaceous carcinoma originates from sebaceous glands either in the tarsal plate (meibomian gland) or associated with eyelashes (glands of Zeis) and is capable of producing widespread metastasis resulting in death. Muir-Torre syndrome is a syndrome of sebaceous tumors associated with visceral malignancy. Except for chronic, unilateral blepharitis, owing to the peculiar manner of spread of this tumor in the plane of the skin epithelium (pagetoid spread) without causing the formation of nodules, few symptoms occur early in the course of the disease. The tumor may progress to involve the tarsal conjunctiva, the bulbar conjunctiva, and even the corneal epithelium. A characteristic sign is regional loss of eyelashes. When the mass thickens, it may have the appearance of a chalazion; a history of multiple chalazia in the same region of the eyelid is suggestive of sebaceous carcinoma and warrants a diagnostic biopsy. Diagnostic delay is common because the lesion often has only modest clinical features.

Treatment is complete surgical excision. Map biopsies to determine the extent of tumor spread can be useful for definitive surgical planning. Topical mitomycin C has been suggested as treatment for pagetoid invasion of the conjunctiva. Cryotherapy also can be a useful adjuvant to surgery for eyelid and conjunctival lesions. In advanced cases, removal of the eyelids, eye, and orbital contents (exenteration) may be necessary. Imaging for local and distant metastases is critical.

BASAL CELL CARCINOMA

Basal cell carcinoma (E-Fig. 391-2), which originates from the basal cell layer of the epithelium, is the most common cutaneous malignancy (Chapter 188). The lesion, which usually is asymptomatic, is often a well-demarcated, elevated nodule that may have a central region of ulceration and fine cutaneous vascular channels (telangiectasias). Occasionally, lesions may be more subtle and present only with eyelid margin thickening, a focal loss or disruption of the eyelashes, or a mild out-turning (ectropion) of the eyelid. A common benign cutaneous lesion, sometimes confused clinically with basal cell carcinoma, is seborrheic keratosis (Chapter 407), which tends to be soft and appear hyperpigmented; the most common site is the lower eyelid, especially in the nasal quadrant. Basal cell carcinoma, particularly near the medial canthus, may extend posteriorly into the soft tissues of the orbit. Imaging before surgical excision for medial canthal lesions may be necessary to determine the true extent of the tumor. Basal cell carcinoma is treated by surgical excision, using the Mohs technique with intraoperative histologic evaluation to determine adequate margins of excision, if possible.

Metastasis is extremely rare. With early detection and adequate excision of the local lesion, the prognosis is excellent.

EYELID SQUAMOUS CELL CARCINOMA

Eyelid squamous cell carcinoma, which is much less common than basal cell carcinoma, arises from the surface squamous epithelium. Ultraviolet light exposure is the major risk factor. In contrast to basal cell carcinoma, squamous cell carcinoma can metastasize, most often to regional lymph nodes. It also can invade the orbit and cavernous sinus via perineural spread from untreated lesions on the eyelids. Treatment is surgical excision, often with the Mohs micrographic surgical technique. Except in rare circumstances, such as in immunosuppressed patients or patients with xeroderma pigmentosa, the prognosis is excellent.

OCULAR SURFACE ABNORMALITIES

DRY EYES

Even minor disturbances in the tear film can cause itching, burning, a foreign body sensation, and transient changes in vision.[3] Dry eyes that cause conjunctival hyperemia without purulent discharge particularly disturb some patients. Paradoxically, decreased tearing can result in irritation and secondary increased (reflux) tearing.

Most daily tear production is not by the lacrimal gland but by small collections of lacrimal glands, mucus-producing glands, and sebaceous glands located throughout the conjunctiva, eyelid, and anterior orbital soft tissue. Over time, particularly in women, production of tear film diminishes. Because tear film production is lower during sleep, patients often note symptoms on awakening followed by slow resolution over minutes or hours. Wind and low-humidity environments, such as in commercial airliners, can exacerbate symptoms. The reduction in aqueous components of tears is often associated with a compensatory increase in mucus production, which tends to blur vision until the patient blinks or uses supplemental tears. These symptoms are particularly prominent in persons who have autoimmune diseases, including rheumatoid arthritis (Chapter 243), Sjögren syndrome (Chapter 247), Stevens-Johnson syndrome (Chapter 407), and ocular cicatricial pemphigoid.

Dry eye disease can be divided by etiology into aqueous tear deficiency and evaporative tear dysfunction. Evaporative tear dysfunction is most commonly secondary to tear film instability and is the result of meibomian gland dysfunction (Fig. 391-10).

Treatment is not definitive and is often not satisfactory.[4] No medication increases the production of tears. Low-viscosity artificial tears (e.g., polyethylene glycol 400 0.4%), which do not tend to blur vision but have a short duration of action, are best used during visually important tasks. High-viscosity tears (e.g., carboxymethylcellulose sodium) have a longer duration of action but tend to blur vision; they are best used at bedtime to maintain lubrication of the ocular surface during sleep. When artificial tears do not control symptoms, occlusion of the nasolacrimal duct with synthetic plugs or permanent surgical occlusion tends to retain the tears that are produced. Anti-inflammatory drugs (e.g., cyclosporine 0.05% drops, every 12 hours indefinitely) can preserve glandular tissue that may be affected by local inflammation. Topical lifitegrast, given topically twice daily indefinitely, is also thought to work through anti-inflammatory mechanisms by inhibiting T-cell activation. For patients with systemic disease associated with dry eyes, effective treatment of the systemic disease sometimes improves the eye abnormalities.

PINGUECULA AND PTERYGIUM

A pinguecula (Fig. 391-11) consists of a limbal (at junction of cornea and sclera) and bulbar conjunctival degenerative process caused by ultraviolet light damage to the subepithelial tissue. It is very common and rarely causes symptoms. If the supportive tissue degeneration extends into the cornea, it becomes a pterygium (Fig. 391-12), which may cause corneal astigmatism and require surgical excision. About 2 to 10% with a pterygium have a coexisting squamous carcinoma, which often is clinically unsuspected and diagnosed only by histopathologic examination.

RECURRENT EROSION

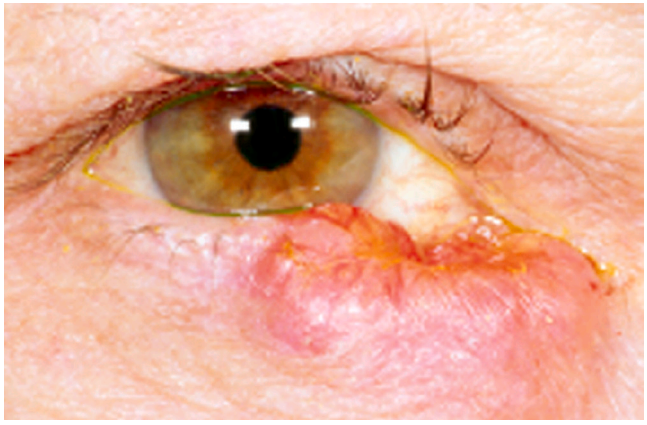
Recurrent corneal erosion most often manifests as a delayed reaction to a minor traumatic corneal abrasion. The abrasion heals abnormally, resulting in a weakness of the epithelial attachment to its underlying tissue. Weeks to months to years later, the patient awakens with ocular pain on opening the eye, sometimes with recurrent episodes of pain every morning. The epithelium has become "stuck" to the overlying upper lid and is mechanically abraded. The condition is treated with hyperosmotic drops as well as lubrication with either wetting drops or ointment. If the erosions continue to occur despite drops and ointment, surgical options include superficial keratectomy (in which the epithelium is mechanically débrided), phototherapeutic keratopathy, or stromal micropuncture. All three techniques work by trying to strengthen the adherence of the weak epithelium to the underlying cornea.

ACCIDENTAL TRAUMA

With ocular trauma, many tissues of the eye can be easily disrupted, and the effects of trauma may not be manifest for months or even years after the episode of trauma. If the traumatic episode disrupts the eye wall (cornea and sclera), surgical repair is necessary, usually urgently. If the eye wall is intact, surgical treatment is often not necessary, at least initially.

CORNEAL ABRASION

The corneal epithelium is very delicate, and contact by any object can result in shearing or irregularity of the epithelium. Corneal abrasion is one of the most common forms of ocular injury. Symptoms are often intense and intolerable. Healing (i.e., re-epithelialization) of the cornea occurs within 24 to



E-FIGURE 391-2. A typical nodular basal cell carcinoma. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology*, 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

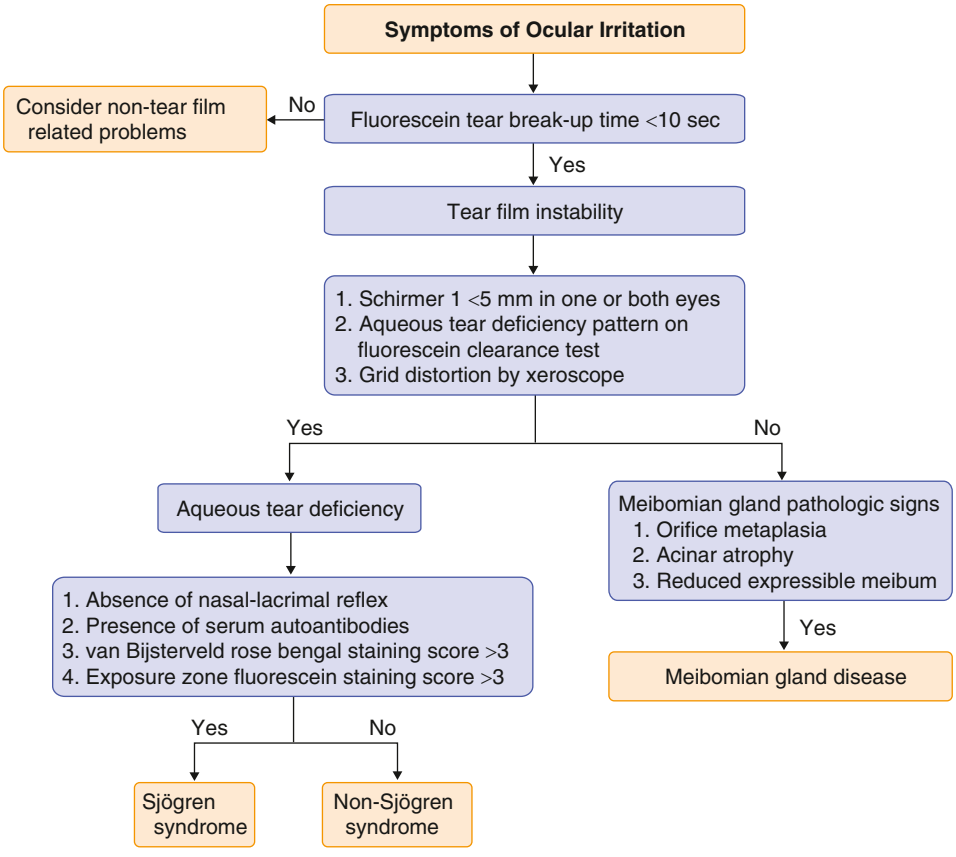


FIGURE 391-10. Diagnostic algorithm for ocular irritation. (Modified from Pflugfelder SC, Tseng SC, Sanabria O, et al. Evaluation of subjective assessments and objective diagnostic tests for diagnosing tear-film disorders known to cause ocular irritation. *Cornea*. 1998;17:38-56.)

FIGURE 391-11. Pinguecula. These lesions are found at the 3-o'clock and 9-o'clock positions and are extremely common, especially in older patients. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology*, 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

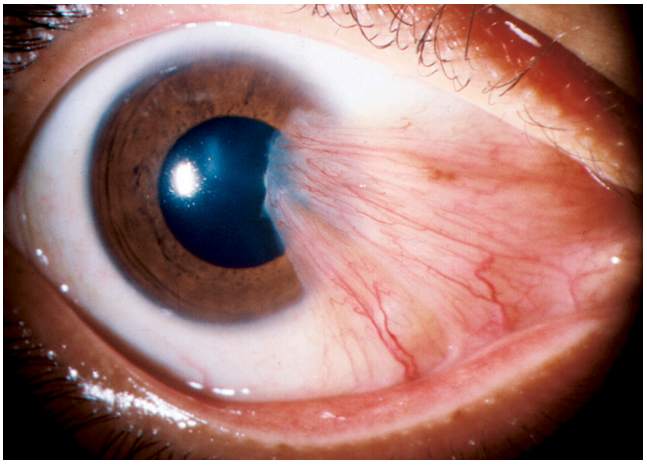

FIGURE 391-12. Pterygium. These lesions are found in the horizontal meridian, most common nasally. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology*, 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

48 hours. Rust from metallic fragments is toxic to the epithelium and should be removed. Bacterial or fungal keratitis may complicate injuries from fingernails or vegetable matter, such as tree branches. Treatment usually consists of a topical antibiotic (e.g., fluoroquinolone antibiotics or antibiotic ointment, four times daily for 10 to 14 days) to prevent bacterial keratitis. Subsequent scarring usually does not occur unless deeper structures, such as the Bowman membrane, are affected. Topical anesthetics never should be prescribed to control pain because they increase the risk for microbial keratitis and scarring and may delay healing.

MAJOR OCULAR TRAUMA

Hyphema (Fig. 391-13) is hemorrhage into the anterior chamber usually caused by blunt trauma. If the patient is supine, such as in an intensive care unit, the blood will distribute uniformly over the iris to cause the appearance of increased pigmentation of the iris (heterochromia iridis). If the patient has been sitting, the blood may settle by gravity to form an aqueous-blood interface with the blood in the dependent portion of the anterior chamber. Hyphema, which is a sign of serious ocular damage, may lead to secondary glaucoma and blood staining of the cornea. It requires prompt evaluation by an ophthalmologist.

The most common site of rupture of a globe is at the limbus (junction of cornea and sclera), where a pigmented mass may be noted. The mass may be either a blood clot or an anteriorly displaced uveal tract (usually iris). Any manipulation of the globe may force the remaining intraocular tissue through the wound and may make the injury irreparable. Emergent surgical repair is usually indicated.

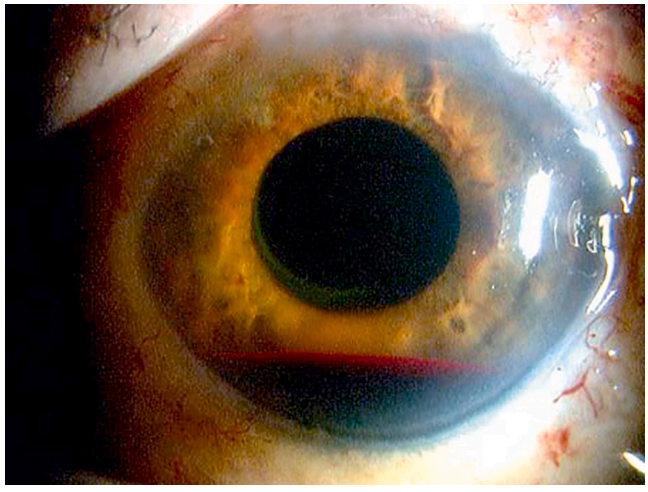

FIGURE 391-13. Hyphema. (Courtesy of Edward S. Harkness Eye Institute, Columbia University.)

Cataract and retinal detachment are not common except in severe accidental trauma. A unilateral cataract or unilateral glaucoma may occur decades after the injury, even when an injury is too minor to be recalled. Traumatic cataract and traumatic glaucoma are treated in the same manner as other forms of these conditions.

INFLAMMATORY EYE DISORDERS

UVEITIS

Inflammation of any part or parts of the uveal tract (iris, ciliary body, and choroid) is called uveitis, iritis, iridocyclitis, or choroiditis, depending on the extent of the involvement of the anterior and posterior segments of the eye. Symptoms include a red eye (see Table 391-4), decreased vision, and photophobia. The inflammation may be acute or chronic, and an underlying systemic cause is found in approximately 50% of cases. Uveitis accompanies many autoimmune diseases, often without correlation to the activity of the systemic inflammation. Anterior uveitis or conjunctivitis is nearly universal in patients with reactive arthritis (Chapter 244). About 25% of patients with ankylosing spondylitis (Chapter 244) develop acute, recurrent anterior uveitis. Two to 12% of patients with inflammatory bowel disease (Chapter 127) develop anterior uveitis, which is also common with psoriatic arthritis but not with psoriasis alone (Chapters 244 and 405). Treatment with topical corticosteroids (e.g., prednisolone acetate 1%, one drop in the affected eye or eyes every 1 to 6 hours while awake) is often sufficient to control ocular disease, but some patients will require more aggressive local therapy, including intravitreal or periocular steroid injections. Systemic immunosuppression[5,6] with oral corticosteroids (e.g., 10 to 35 mg prednisone daily)[A3] or steroid-sparing immunosuppressive agents (e.g., methotrexate 25 mg weekly, mycophenolate mofetil 39 mg daily,[A4] or adalimumab 80 mg loading dose then 40 mg every 2 weeks)[A5,A6] is an effective alternative that also may be necessary to reduce flares and visual loss in patients with chronic disease.

ENDOPHTHALMITIS

Endophthalmitis is extensive inflammation within the eye from any cause. Most cases of endophthalmitis involve a breach in the eye wall (cornea and sclera), associated with either trauma or surgical procedures (incidence of approximately <0.03%). The initial symptom is usually decreased vision followed by ocular pain. The initial sign is often evidence of inflammatory cells either within the aqueous (anterior uveitis) or within the vitreous (vitritis). The cells can be seen only by slit lamp biomicroscopy. Common microbial organisms include toxin-producing gram-positive species and gram-negative species that are often associated with rapidly destructive course. Other organisms of relatively low virulence, *Propionibacterium acnes* and *Staphylococcus epidermidis*, follow a more indolent course with less potential destruction. Metastatic endophthalmitis infection from a primary source outside of the eye is an unusual cause.

Diagnosis is established by sampling anterior chamber fluid or preferably vitreous fluid (vitreous tap) and evaluation of that fluid by Gram stain and culture. Prophylaxis against endophthalmitis includes preoperative topical instillation of povidone-iodine, perioperative topical antibiotics, and intracameral antibiotic injection at the end of cataract surgery.

Systemic antibiotics are not generally effective. Initial management is with intravitreal antibiotics (e.g., commonly used, but not limited to, vancomycin 1 mg/0.1 mL and ceftazidime 2.25 mg/0.1 mL) and, in certain instances, corticosteroids. If there are external signs of infection (e.g., corneal ulcer), topical antibiotics are also used simultaneously. Severe cases may require surgical debulking of the infection (vitrectomy) to reduce the microbial and inflammatory debris burden and to treat associated vitreoretinal pathology.

ALLERGIC CONJUNCTIVITIS

Allergic conjunctivitis (Table 391-6) is commonly associated with atopy, hay fever, and allergic rhinitis.[7] Itching, a foreign body sensation, and a watery discharge are common. Treatment includes cool compresses and topical antihistamines (e.g., olopatadine, once to twice per day until symptoms resolve). Long-term treatment with mast cell stabilizers (e.g., pemirolast drops, four times daily during the allergic season) or the combination of an antihistamine plus a mast cell stabilizer (e.g., olopatadine drops, two times daily during the allergic season) can be extremely effective in treating chronic symptoms. Oral antihistamines (e.g., cetirizine 5 to 10 mg per day until symptoms resolve) can also be useful.

INFECTIOUS EYE DISORDERS

CELLULITIS

Preseptal cellulitis (Fig. 391-14) is soft tissue inflammation of the eyelid anterior to the orbital septum. The orbital septum divides the soft tissues of the eyelid from the soft tissues of the orbit. Orbital tissue is more susceptible to damage by the inflammation than is the preseptal tissue.

The clinical signs of preseptal cellulitis include soft tissue swelling, hyperemia, and conjunctival edema (chemosis). Movement of the eye is not restricted. Extension of inflammation posterior to the orbital septum is indicated by proptosis of the globe and ophthalmoplegia (restricted ocular motility). Treatment of preseptal cellulitis includes oral antibiotics (e.g., commonly used, but not limited to, amoxicillin-clavulanate, 500 mg orally every 8 hours for 10 days, or Bactrim, 500 mg orally twice a day for cases of suspected methicillin-resistant *S. aureus* [MRSA]). Treatment of orbital cellulitis, which can lead to septic optic neuritis, intracranial spread, and cavernous sinus thrombosis, may require intravenous antibiotics and surgical drainage of a paraorbital abscess.

ADENOVIRAL CONJUNCTIVITIS

Viral conjunctivitis (Fig. 391-15) is commonly (see Table 391-6) caused by adenoviruses (especially subtypes 7, 11, and 18). The condition is highly contagious through direct contact or inhalation of respiratory particles. After an incubation period of 3 to 7 days, the patient presents with red eyes (see Table 391-4), itching, burning, foreign body sensation, and often a watery discharge, which persist for 5 to 15 days. Preauricular lymphadenopathy may be present, and a history of upper respiratory tract infection is common. The disease is self-limited, and treatment is aimed at patients' comfort. Cool compresses are often soothing. Patients are advised to wash their hands frequently to prevent spread to others. Topical antibiotics are not required.

BACTERIAL CONJUNCTIVITIS

About 5 to 15% of cases of conjunctivitis in adults are caused by bacteria, mostly *Staphylococcus, Haemophilus*, or *Streptococcus* species.[8] Patients have a mucoid or purulent discharge (Fig. 391-16), often with crusting and edema of the conjunctiva (chemosis) and lids. Bacterial conjunctivitis responds to broad-spectrum antibiotic solutions or ointments (e.g., topical erythromycin ointment three times daily for 2 weeks) (Table 391-7).

CHLAMYDIAL CONJUNCTIVITIS

Adult inclusion conjunctivitis is a chronic conjunctivitis caused by sexual transmission of *Chlamydia trachomatis* (Chapter 294). Patients often have preauricular lymphadenopathy. Oral erythromycin (500 mg orally, four times daily for 7 days) or azithromycin (1 g orally twice daily for 7 days) is required. Trachoma, which is a chronic cicatricial conjunctivitis after repeated chlamydial infection (Chapter 294), is the world's leading cause of corneal blindness. It causes an entropion, inversion of the eyelashes (trichiasis), corneal vascularization, and opacification. Topical erythromycin or tetracycline, twice daily for 3 to 4 weeks, can be effective, but epilation or surgical eyelid reconstruction may be required.

TABLE 391-6 OPHTHALMIC DISORDERS ASSOCIATED WITH CONJUNCTIVITIS

DISORDER	ACUTE OR CHRONIC	UNILATERAL OR BILATERAL	KEY SYMPTOMS	DEGREE OF INJECTION	DISCHARGE TYPE	OTHER FEATURES
Viral conjunctivitis	Acute	Bilateral, possibly asymmetrical	Itching, burning, soreness	4+	Watery	Preauricular lymphadenopathy
Bacterial conjunctivitis	Acute	Unilateral or bilateral	Burning	3+	Heavy, mucopurulent	Lids possibly adherent
Chlamydial conjunctivitis	Subacute, chronic	Usually unilateral	Burning, irritation	2+	Scant, mucopurulent	Usual occurrence in young, sexually active adults
Herpes simplex conjunctivitis	Acute	Unilateral	Photophobia, irritation	1-2+	None	Dendritic ulcer on the cornea or vesicles on the lid possible
Allergic conjunctivitis	Chronic	Bilateral	Itching	2+	Stringy, mucoid	Usual occurrence in atopic persons, possible seasonal symptoms
Blepharitis	Chronic	Bilateral	Itching, burning, foreign body sensation	1-2+	Usually none	Inflammation and crusting of lid margins
Dry eye	Chronic	Bilateral	Foreign body sensation	1+	Mucoid in severe cases	Punctate fluorescein staining of the cornea

TABLE 391-7 TOPICAL ANTIBIOTICS FOR EYE INFECTIONS

DRUG	TYPE	CONCENTRATION	DOSE
Moxifloxacin	Drops	0.5%	1 drop bid × 7 days
Gatifloxacin	Drops	0.5%	1 drop q2h × 24 hours; then qid × 6 days
Ciprofloxacin	Drops	0.3%	1 drop q2h × 48 hours; then q4h × 5 days
Gentamicin	Drops	0.3%	1 drop four times daily
Ofloxacin	Drops	0.3%	1 drop q2h × 48 h; then qid × 5 days
Bacitracin	Ointment	500 U/g	Put in eye, for several days
Tobramycin	Ointment	0.3%	Put in eye, for several days
Erythromycin	Ointment	0.5%	Put in eye, for several days

bid = twice a day; qid = four times a day.

HERPES SIMPLEX KERATITIS

Herpes simplex keratitis is the most common cause of a central corneal ulcer (Fig. 391-17).[9] Herpes simplex virus also can cause vesicular eyelid dermatitis. Initially, the main signs of primary herpes simplex keratitis are a red eye and a corneal epithelial dendritic ulcer. With appropriate antiviral therapy (e.g., ganciclovir 0.15% ophthalmic gel five times daily for at least 1 week or oral acyclovir 800 mg five times per day for 7 to 10 days), the keratitis usually heals without scarring. Herpes simplex keratitis can recur and may extend into the corneal stroma and cause a red eye, ocular discomfort, blurred vision, and corneal scarring. Patients with recurrent disease may benefit from chronic low-dose antivirals (e.g., oral acyclovir 800 mg per day indefinitely) for suppression. Stromal involvement is multifactorial and can be recalcitrant. Corneal transplantation is occasionally needed for scarring, but success is often limited by recurrence in the donor tissue.

HERPES ZOSTER OPHTHALMICUS

Herpes zoster ophthalmicus (shingles, Chapter 346) has a propensity to involve one or more branches of the trigeminal nerve. The virus also can affect the

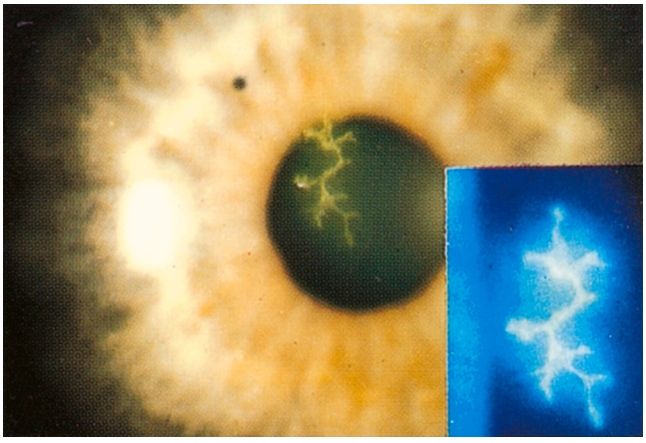

FIGURE 391-17. Herpes simplex corneal epithelial keratitis in diffuse light and in light passed through a cobalt blue filter after fluorescein staining *(inset)*. Note the dendritic staining pattern characteristic of herpes simplex.

uveal tract and, in immunosuppressed patients, the retina (i.e., acute retinal necrosis). When the trigeminal nerve is involved, spread to the inside of the eye (uveitis) is most likely if vesicles are present in the inner corner of the eyelids or on the nose, especially the tip of the nose (Hutchinson sign). If the uvea is not involved, the skin lesions heal with some scarring but no long-term effects. In patients with moderate to severe skin involvement, treatment can be started with oral acyclovir (800 mg orally five times per day for 7 to 10 days) or valacyclovir (1 g three times a day for 10 to 14 days). If uveitis develops, the treatment (e.g., prednisolone acetate drops 1% four times daily and atropine 1.0% once or twice daily) can be extended and difficult. Like herpes simplex virus, herpes zoster can affect the cornea, and patients should be monitored for recurrent disease.

PSEUDOMONAL AND GONOCOCCAL KERATITIS

Keratitis, which is inflammation of the corneal stroma, can be caused by spread of pathogens internally from a corneal ulcer. *Pseudomonas aeruginosa* (Chapter 282), which causes a particularly virulent keratitis, is the most common gram-negative pathogen and is especially common in people who wear contact lenses. To avoid intraocular spread, urgent and aggressive antibiotic treatment is necessary (e.g., fortified tobramycin [9 mg/mL] or a fourth-generation fluoroquinolone (e.g., moxifloxacin), every hour for 3 to 7 days. The dosage and duration of the treatment depend on the response.

Another gram-negative cause of a virulent keratitis is *Neisseria gonorrhoeae* (Chapter 274), especially in neonates. Corneal infection is accompanied by copious tearing and a characteristic hyperpurulent discharge. Prompt treatment with topical irrigation (normal saline to remove mucopurulent material) and penicillin G (100,000 units/kg/day given intravenously in four divided doses for 7 days) is essential to prevent corneal perforation.

CYTOMEGALOVIRUS RETINITIS

Cytomegalovirus retinitis (Chapter 347) is unusual except in immunosuppressed patients and human immunodeficiency virus (HIV) infection but is increasing among patients who have undergone solid organ or hematopoietic stem cell transplantation. Clinically, a central retinochoroiditis is seen. The presumptive diagnosis is made on the characteristic intense, wedge-shaped reaction in the retina, with considerable exudates and hemorrhages, giving the terms "pizza pie retinitis" and "hemorrhagic cottage cheese retinitis" to the entity. Treatment is with antiviral drugs: ganciclovir (5 mg/kg intravenously twice daily, two to three times per week), foscarnet (90 mg/kg intravenously twice daily, twice per week), or cidofovir (5 mg/kg intravenously, weekly for 3 weeks) with follow-up maintenance. Intravitreal injections with an appropriately reduced dose are also used in selected cases.

ACANTHAMOEBA KERATITIS

Acanthamoeba species (Chapter 323) can cause a severe, blinding keratitis. The wearing of contact lenses is a major risk factor. A characteristic stromal ring infiltrate develops, and uveitis may occur. When patients are examined early in their disease course, they may only have a slight epitheliopathy and have pain out of proportion to findings on examination. A history of swimming or using fresh water to cleanse or store contact lens often can be elicited. Using a confocal microscope, the acanthamebic parasite can be observed clinically as a pear-shaped cyst (11 to 15 μm). Numerous treatment protocols exist (e.g., polyhexamethyl biguanide 0.02% drops every hour). The duration and dose depend on the response. Corneal transplantation may be necessary in cases of severe corneal scarring.

TOXOPLASMIC RETINITIS

Toxoplasma gondii (Chapter 320) causes both a congenital and an acquired retinochoroiditis, which is more common in immunosuppressed patients. The lesions begin as an acute retinitis that atrophies centrally and pigments peripherally as it heals (Fig. 320-2). The protozoa are found both in free and encysted forms within the retina. The condition may be self-limited and diagnosed as a healed incidental finding that does not need treatment. Standard treatment of vision-threatening toxoplasmosis remains controversial. When active lesions are in the macula or a severe vitritis causes at least a two-line decrease in vision, 4 to 6 weeks of quadruple therapy (pyrimethamine, 200 mg oral loading dose, then 25 mg orally daily; folinic acid, 10 mg orally every other day; sulfadiazine, 2 g oral loading dose, then 1 g four times daily; and oral corticosteroids; e.g., prednisone, 20 to 60 mg orally daily beginning at least 24 hours after antibiotic therapy is started and tapered 10 days before stopping antibiotics) usually produces good results. Alternative regimens may include trimethoprim-sulfamethoxazole (800/160 mg orally twice daily), clindamycin (150 to 450 mg orally three to four times daily), or atovaquone (1 g oral loading dose, then 500 mg daily).

FUNGAL ENDOPHTHALMITIS

Fungal endophthalmitis is infrequent (7% of microbial endophthalmitis) but is a potentially disastrous infection of the inside of the eye, often leading to blindness. The primary organisms are *Candida, Coccidioides*, and *Aspergillus* species, which can gain access inside the eye either by traumatic introduction or through hematogenous spread. The patient presents with floaters and/or decreased vision. In advanced cases, the patient develops red eye and ocular pain. Multiple abscesses tend to be caused by fungi, whereas a solitary abscess is more likely caused by bacteria. Systemic antifungal agents (e.g., fluconazole 100 to 200 mg daily for 2 months) are often effective in treating localized fungal abscesses, but if the infection has progressed into the vitreous body, vitrectomy and intravitreal antifungal therapies are indicated.

TUBERCULOSIS

About 1% of patients with pulmonary tuberculosis (Chapter 299) have uveal involvement, usually as iridocyclitis or diffuse choroiditis. Painless progressive visual loss is the most common symptom. Small yellow choroidal lesions may be seen, and retinal periphlebitis may occur secondarily. Treatment is as for the primary disease.

SYPHILIS

About 5% of patients with secondary syphilis (Chapter 295) develop anterior uveitis or neuroretinitis. In tertiary syphilis, the miotic Argyll Robertson pupil reacts poorly to light but briskly to accommodation. Treatment is as for the systemic disease.

STRUCTURAL AND AGE-RELATED DISORDERS

CATARACT

A cataract is an opacification of the crystalline lens. The lens doubles in volume between birth and age 70 years as new lens "fiber cells" are laid down on the external aspect of the lens cortex, beneath the lens capsule. The older fibers in the center of the lens cannot be desquamated into the surrounding aqueous and thus are compressed into the center of the lens. At birth, the lens is pliable and totally transparent. By age 45 years, the lens loses its pliability, which compromises near vision. As the process progresses, the lens loses its transparency, beginning at the center of the lens (nuclear sclerosis). The concurrent change in density of the lens nucleus may alter the optical characteristics of the eye to cause acquired nearsightedness ("second sight"). Ultimately, the cataract may become so dense that cataract surgery is necessary to restore vision.

Symptoms are typically loss of vision, especially at night, and glare.[10] Cataract surgery, performed as an outpatient, is elective and depends on how much the decreased vision interferes with the normal lifestyle of the patient. A synthetic intraocular lens implant is inserted into the eye during surgery. Standard phacoemulsification provides results as good as femtosecond laser treatment.[A7]

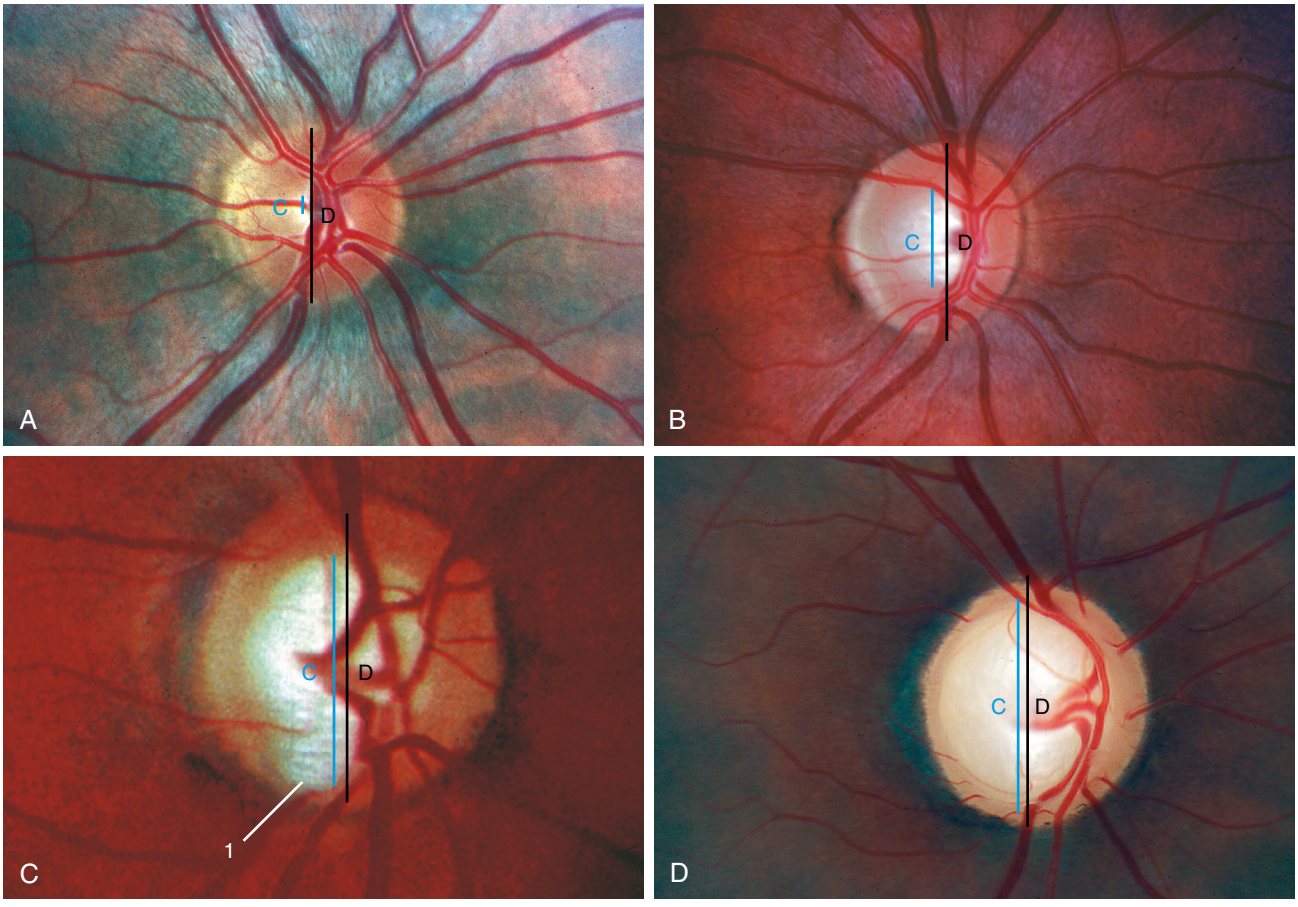

FIGURE 391-18. **Cup-to-disc ratios. A,** Normal cup-to-disc (C/D) ratio of 0.1. **B,** Likely normal C/D ratio of 0.5. **C,** C/D ratio of 0.8 vertically with inferior notching (1) of the nerve (glaucomatous change). **D,** C/D ratio of 0.90 vertically (glaucomatous change). C = cup; D = disc. (From Palay DA, Krachmer JH. *Primary Care Ophthalmology*, 2nd ed. Philadelphia: Elsevier Mosby; 2005.)

Prognosis for restoration of vision is excellent, depending on the function of the retina. In general, cataracts develop asymmetrically, and the worst eye (vision-wise) should have surgery first. As the second eye's cataract worsens, decreasing vision and monocularity are indications for cataract surgery in the second eye.

GLAUCOMA

Glaucoma is an optic neuropathy in which progressive damage to retinal ganglion cells and their axons results in the characteristic loss of optic nerve tissue and damage to the peripheral and central visual field.[11] The primary site of damage is at the lamina cribrosa, where the axons of the optic nerve leave the eye.

Aqueous humor is produced by the nonpigmented ciliary epithelium of the pars plicata of the ciliary body. Aqueous fluid leaves the eye through the trabecular meshwork and uveoscleral pathways into the venous circulation. If the drainage function does not match production, the intraocular pressure increases. If the elevated intraocular pressure is high enough or is present long enough, ganglion cells in the retina are damaged, causing loss of their axons. Loss of axons can best be appreciated clinically at their normal exit from the eye, the optic disc. Bulk loss of axons will lead to enlargement of the optic cup, which is recorded as increase in the cup-to-disc ratio.

Intraocular pressure is the principal risk factor for the onset and progression of glaucoma. In general, the higher the pressure, the greater is the risk. An intraocular pressure greater than 2 standard deviations above the population mean (21 mm Hg) is termed *ocular hypertension,* but no intraocular pressure is fully protective, and many individuals develop glaucoma despite a statistically normal intraocular pressure. Additional risk factors for glaucoma include African ancestry, older age, low blood pressure, genetic predisposition, myopia, hemorrhages on the anterior surface of the optic nerve (disc hemorrhage), and anterior segment abnormalities.

In open-angle glaucoma, there is apparent free anatomic access to the trabecular meshwork. In closed-angle glaucoma, there is a relative or absolute anatomic barrier to the flow of aqueous. For most individuals, glaucoma is asymptomatic until late in the disease, and the only way to detect it is by an ophthalmologic examination.

PRIMARY OPEN-ANGLE GLAUCOMA

The most common type of glaucoma in elderly people is primary open-angle glaucoma. For many patients, the first symptom may be difficulty reading, loss of contrast sensitivity, or glare. Peripheral visual fields may be reduced considerably before the patient notes loss of function. Most cases of primary open-angle glaucoma are identified during routine eye examinations, either by discovery of abnormally high intraocular pressure or by the presence of a high cup-to-disc ratio (Fig. 391-18). Although the U.S. Preventive Services Task Force has determined that evidence is insufficient to assess the benefits of screening for open angle glaucoma,[A8] testing is routine during most ophthalmologic examinations in adults. Average intraocular pressure is generally at or below 21 mm Hg, but exceptions exist depending on corneal thickness (causing artifacts of measurement in patients with excessively thin or thick corneas) and genetic disposition. The diagnosis of glaucoma is confirmed by characteristic visual field loss as determined by automated perimetry.

The treatment goal is to reduce intraocular pressure, initially with pharmacologic agents: β-blockers (e.g., timolol drops 0.5% twice daily), carbonic anhydrase inhibitors (e.g., dorzolamide drops three times daily), α-agonists (e.g., brimonidine drops three times daily), prostaglandin analogues (e.g., travoprost 0.004% or latanoprost 0.005% drops once daily), and rho-kinase inhibitors (e.g., netarsudil 0.02% drops once daily). Generally, the drops are taken for a lifetime. Applying energy to the structures of the trabecular meshwork with a laser (laser trabeculoplasty) often results in years of control of intraocular pressure, and this procedure may be considered first-line therapy, because it can maintain normal pressure without medications.[A9] In resistant cases, mechanical filtration is accomplished surgically by bypassing the trabecular meshwork either by creating a fistula (trabeculectomy) between the anterior chamber and the episcleral tissue or by implanting a synthetic filtration device (a tube-shunt)[A10] from the anterior chamber through the sclera into a collection reservoir located behind the equator of the eye in the soft tissues of the orbit.

SECONDARY OPEN-ANGLE GLAUCOMA

Secondary causes of elevated intraocular pressure also can lead to glaucomatous nerve damage. The most common is pseudoexfoliation syndrome, a genetically

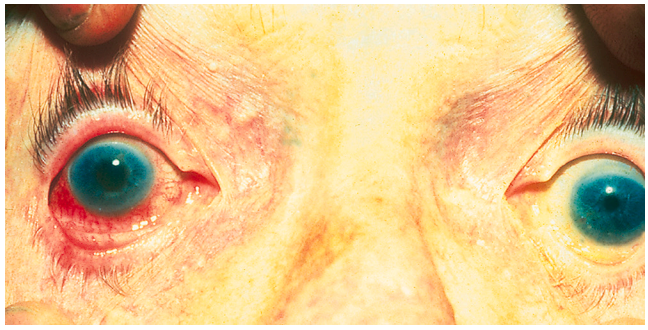

FIGURE 391-19. Acute angle-closure glaucoma. The left eye is normal. The red right eye has a nonreactive, mid-dilated pupil. (Courtesy of Dr. Myron Yanoff.)

determined biochemical abnormality of the basement membrane protein, fibrillin. The syndrome occurs among people throughout the world but is especially prominent in Scandinavians and Saudi Arabians. Affected individuals are identified by accumulation of abnormal fibrillogranular material (exfoliative material) on the surface of the crystalline lens, most easily seen in the pupillary space or pupillary border. Pseudoexfoliative glaucoma greatly increases the risk for developing open-angle glaucoma. Treatment is as for open-angle glaucoma.

ANGLE-CLOSURE GLAUCOMA

An acute attack of angle-closure glaucoma (Fig. 391-19) may occur over a short period of time and cause extreme, debilitating symptoms. Alternatively, symptoms may develop over a long period of time with few specific symptoms.

The risk factors for angle-closure glaucoma are based on the anatomic configuration of the components of anterior chamber. Persons who are farsighted (hyperopia) have a shortened anterior-to-posterior axis of the eye, indicated clinically by a shallow anterior chamber that may be noted with penlight illumination but often requires slit lamp examination. As the crystalline lens increases in volume with time, the iris is displaced anteriorly. At some point, the posterior surface of the iris may come in relatively tight contact with the anterior surface of the lens. Aqueous flow is restricted, and fluid accumulates in the posterior chamber, where it displaces the diaphanous peripheral iris anteriorly. When the peripheral iris comes in contact with the posterior cornea, the anterior chamber angle is suddenly occluded, thereby preventing egress of aqueous humor via the trabecular meshwork. Acute angle-closure may be precipitated by pharmacologic dilation of the pupil. Patients who are farsighted (hyperopia) or have cataracts should be dilated with caution. The intraocular pressure may increase from normal levels (10 to 20 mm Hg) to greater than 60 mm Hg (nearly equaling diastolic arterial pressure). The symptoms of acute angle closure may include extreme pain, which may be poorly localized to the eye, as well as nausea and vomiting. Persistent vomiting may cause abdominal pain, thereby simulating an acute abdomen.

Initial treatment is with topical (e.g., timolol 0.5% in one dose) and systemic pressure-lowering agents (e.g., carbonic acetazolamide, 250 to 500 mg intravenously or two 250-mg tablets orally in one dose if intravenous access or drug is not available), followed by creation of a fistula in the peripheral iris with a laser (laser iridotomy) between the posterior chamber and the anterior chamber to bypass the obstruction. Most patients require a laser iridotomy prophylactically in the second eye to prevent angle-closure glaucoma. Another potential option is lens extraction because age-related growth in the lens contributes to angle closure.

Secondary glaucoma may also occur after intraocular hemorrhage, intraocular trauma, and intraocular inflammation. Some developmentally related secondary glaucomas, such as the iridocorneal endothelial syndrome, may not become evident until adulthood.

RETINAL DETACHMENT

A retinal detachment is a separation of the neural (sensory) retina from the underlying retinal pigment epithelium. The main types are rhegmatogenous, caused by a retinal tear or hole, as typically occurs with a posterior vitreous detachment; tractional, caused by fibrosis, such as in advanced proliferative diabetic retinopathy; or serous, when fluid accumulates under neural retina because of breakdown of the blood-retinal barrier in conditions such as malignant hypertension or eclampsia of pregnancy.

The classic symptoms are a sensation of flashes of light, floaters in the involved eye owing to the causative vitreous detachment, and a shadow in the field of vision. Urgent treatment usually is needed to prevent macular involvement or deterioration. Most cases require a scleral buckle and/or vitreous surgery, although select cases may be successfully treated by in-office procedures such as laser photocoagulation and pneumatic tamponade. The latter involves the intravitreal injection of a gas bubble that, with proper head positioning on the part of the patient, effectively closes a retinal break; permanent sealing of the break is accomplished laser photocoagulation. In contrast, serous retinal detachments generally resolve without direct intervention when the underlying cause is successfully treated.

AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration is a neurodegenerative disease that initially affects the retinal pigment epithelium of the macula, mainly in the sixth to ninth decades of life.[12–14] About 8.5% of the world's blindness is caused by age-related macular degeneration, mainly in industrialized countries. In the United States, age-related macular degeneration affects more than 1.75 million persons, and its prevalence increases with each decade after the age of 55 years. The exact genetic influence has not yet been determined, but abnormalities of complement factor H appear to play a role. Environmental factors such as smoking are known to accelerate this degenerative process.

Two forms of age-related macular degeneration predominate: the "dry" or nonexudative type and the "wet" or neovascular type. The dry form usually precedes the wet form, which usually causes the most profound vision loss, especially if untreated.

The first clinical sign of age-related macular degeneration is an attenuated or mottled appearance of the retinal pigment epithelium in the macula, usually accompanied by *drusen,* which are abnormal lipoprotein deposits within the retinal pigment epithelial basement membrane complex (Bruch membrane). Lipofuscin, a complex mixture composed mainly of the oxidation products of polyunsaturated fatty acids and vitamin A dimers, accumulates in stressed retinal pigment epithelial cells. Significant macular degeneration is typically characterized by soft drusen that are greater than 60 μm and appear on examination as deep, hypopigmented spots. This nonexudative age-related macular degeneration may antedate subjective alteration in vision by years to several decades.

Symptoms of age-related macular degeneration are confined to deterioration of central visual function, because the peripheral retina is not involved. As the process progresses, individuals with advanced disease will be able to walk down a street without apparent difficulty (a peripheral retinal function) but will not be able to recognize facial features of people whom they meet (a macular retinal function). Visual aids and other devices, such as special glasses and video-based magnification aids, often allow patients to continue with daily functions and to continue to live independently.

Dry age-related macular degeneration advances at a variable rate (months to decades), during which patients develop retinal features of well-defined pigment loss (geographic retinal atrophy; Fig. 391-20). No current treatment exists for the dry phase of the disease, except for a possible positive influence of dietary supplements (antioxidants). Vitamin supplementation with vitamins C and E, lutein, zeaxanthin, zinc, and copper may retard the progression of moderate age-related macular degeneration to severe age-related macular degeneration. β-Carotene (a vitamin A precursor) of this quantity is not recommended for cigarette smokers because of an increased risk for lung cancer. Cessation of smoking, control of blood sugar, control of blood lipid levels, and control of systemic blood pressure are particularly important behavioral modifications. Patients with dry age-related macular degeneration who are at higher risk for developing choroidal neovascularization should be advised to monitor themselves by means of Amsler grid or similar testing strategies and urgently seek treatment if new visual symptoms develop.

In the "wet phase" of age-related macular degeneration (Fig. 391-21), frail neovascular channels originating from the established vascular system of the choroid may extend through a breach in Bruch membrane into the subretinal space (subretinal or choroidal neovascularization). Spontaneous hemorrhage of the vessels adds to the loss of photoreceptors. Hemorrhage is accompanied by acute, and often permanent, loss of central visual acuity (i.e., the wet phase of age-related macular degeneration). Both eyes are typically affected to a similar degree. Neovascularization can be identified by fluorescein angiography and ocular coherence tomography. Intraocular injections of antivascular endothelial growth factors (e.g., ranibizumab, bevacizumab, or aflibercept)[A11] or a dual inhibitor of angiopoietin-2 and vascular endothelial growth factor A (faricimab)[A12] reduce the risk for visual loss in patients with neovascular age-related macular degeneration and can result in gains in vision, especially when administered on a timely basis. Other treatments include photodynamic therapy or, in advanced cases, vitrectomy to remove massive subretinal hemorrhage.

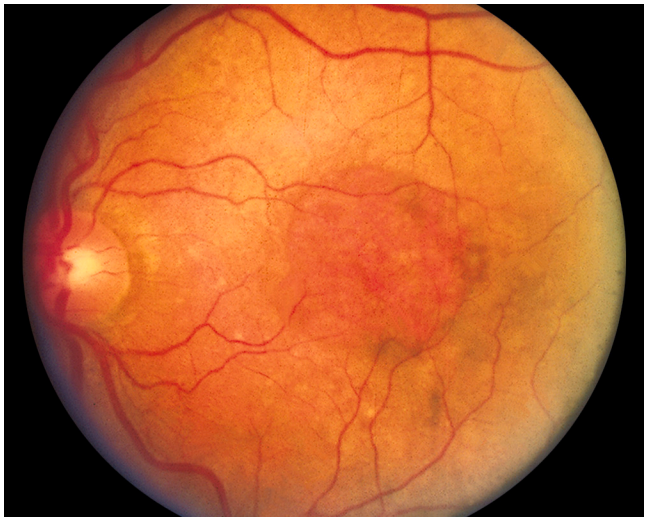

FIGURE 391-20. Dry age-related macular degeneration. Drusen are present in the posterior pole around a large area of geographic atrophy of the retinal pigment epithelium.

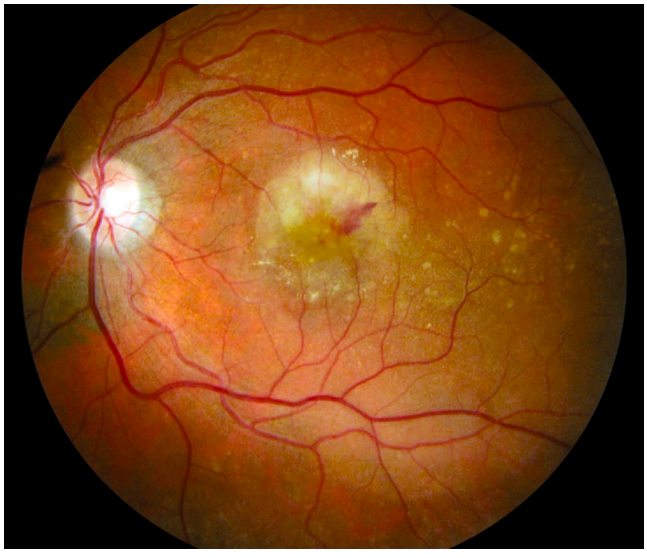

FIGURE 391-21. Wet age-related macular degeneration. A "dirty gray" neovascular membrane is present under the central macular area.

FIGURE 391-22. Background diabetic retinopathy. Exudates, microaneurysms, and small hemorrhages are seen in the posterior pole (left eye).

FIGURE 391-23. Severe nonproliferative diabetic retinopathy with cotton-wool spots, intraretinal microvascular abnormalities, and venous beading. (From Yanoff M, Duker JS, eds. *Ophthalmology*. Philadelphia: Mosby Elsevier; 2009.)

SYSTEMIC DISEASES WITH OCULAR SYMPTOMS DURING ADULTHOOD

DIABETES MELLITUS

Diabetic retinopathy is one of the leading causes of blindness in the United States. Background diabetic retinopathy, with microaneurysms, hemorrhages, exudates (Fig. 391-22), and macular edema, accounts for most cases of decreased vision but rarely causes profound vision loss.[15] With acute hyperglycemia, accumulation of sorbitol may lead to swelling of the lens; secondary refractive errors may persist for 6 to 8 weeks. Most diabetic patients never develop the more severe proliferative diabetic retinopathy (Fig. 391-23), which generally occurs only after 15 years or more of diabetes and causes a profound loss of vision.

Diabetic retinopathy is closely correlated with the duration of diabetes mellitus (Chapter 210). The prevalence of diabetic retinopathy is approximately 27% among patients who have had type 1 diabetes for 5 to 10 years, 70 to 90% among patients who have had diabetes for more than 10 years, and 95% among patients who have had diabetes for 20 to 30 years. In patients with type 2 diabetes (Chapter 210), the prevalence of diabetic retinopathy is about 23% after 12 years and 60% after 16 years. Tight control of blood glucose greatly reduces the risk for the development of diabetic retinopathy.

The treatment of diabetic retinopathy includes control of the diabetes and any hyperlipidemia (Chapter 190). Intensive diabetes therapy (Chapter 210) reduces the risk of future ocular surgery in type 1 diabetes. Antiangiogenic therapy (e.g., ranibizumab, bevacizumab, aflibercept, or faricimab[A13–A17]) is generally as good as or superior to laser therapy for diabetic macular edema and has often replaced it as first-line therapy.[16] However, laser photocoagulation remains particularly useful for proliferative diabetic retinopathy, for clinically significant macular edema that does not involve the foveal center, or when antiangiogenic therapy does not provide a complete response. Intravitreal steroid injection may also be beneficial.

HYPERTENSION

In chronic systemic hypertension (Chapter 64), the characteristic retinal vascular findings can assess the severity of hypertension. As the severity increases, patients develop arterial narrowing, arteriovenous nicking (Fig. 391-24), nerve fiber layer infarcts, and intraretinal hemorrhages. Moderately sclerosed arterioles have a "copper wiring" appearance, whereas severely sclerosed vessels demonstrate "silver wiring." Acute hypertension may cause optic nerve edema ("papilledema"; Fig. 391-25) and serous retinal detachments that usually resolve without significant sequelae if blood pressure is controlled.

OTHER SYSTEMIC DISEASES

In bacterial endocarditis (Chapter 61), emboli may cause retinal hemorrhages or the characteristic Roth spot (Fig. 391-26). Accumulation of copper in the posterior cornea may aid in the diagnosis of Wilson disease (Chapter 195), although its clinical diagnosis usually precedes the characteristic Kayser-Fleischer ring (see Fig. 195-2), which fades after treatment. Tay-Sachs and Niemann-Pick diseases (Chapter 192) are associated with a foveal cherry-red spot owing to the accumulation of gangliosides within perifoveal ganglion cells. Pseudoxanthoma elasticum (Chapter 239) is often associated with characteristic angioid streaks of the retina.

FIGURE 391-24. Hypertension retinopathy with narrowed arterioles whose sclerosed walls create the appearance of "nicking" when the arterioles cross venules. (From Yanoff M, Duker JS, eds. *Ophthalmology*. Philadelphia: Mosby Elsevier; 2009.)

FIGURE 391-25. Papilledema. (Courtesy of Dr. Kathleen Digre.)

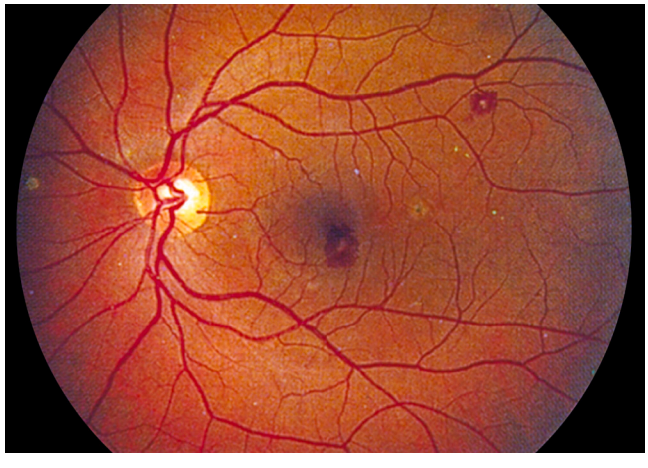

FIGURE 391-26. Roth spots. Multiple white-centered hemorrhages in a man with recurrent subacute bacterial endocarditis. White-centered hemorrhages are also seen with leukemia and diabetes. The small white scars are probably the residua of previous episodes.

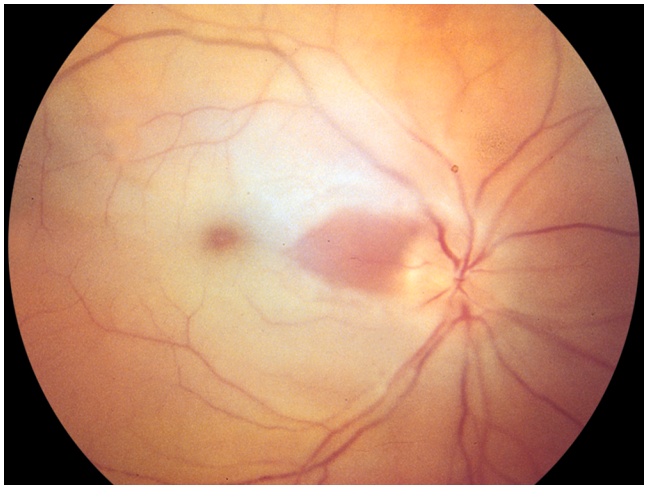

FIGURE 391-27. Central retinal artery occlusion. Fundus photograph shows the fovea, which lacks inner retinal layers, as a cherry-red spot, in contrast to extrafoveal retina, which appears white because of inner retinal infarction. In this case, a small area of retina adjacent to the optic disc is spared, owing to the presence of a cilioretinal artery.

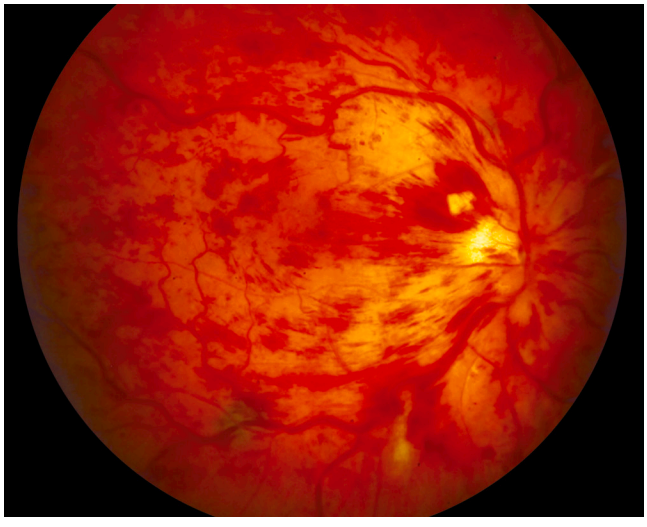

FIGURE 391-28. Central retinal vein occlusion with diffuse intraretinal hemorrhages in all four quadrants.

VASCULAR ABNORMALITIES OF THE EYE

The major vessels of the retina enter the eye at a point of relative constriction in the tissues of the lamina cribrosa of the optic disc. In persons who have generalized vascular disease, particularly systemic hypertension, occlusion of either the artery or vein may lead to a sudden loss of vision.[17] Partial occlusion of either the artery or vein is associated with less visual loss but still increases the risk for developing neovascular glaucoma.

Occlusion of the central retinal artery (Fig. 391-27) presents as painless acute loss of vision. The ischemic retina generally has a pale gray appearance except at the fovea, where the normal color is preserved (cherry-red spot). The clinical appearance of edema resolves over time, but vision generally does not recover.

Venous occlusion of the central retinal vein (Fig. 391-28) presents as painless loss of vision. The appearance of the fundus is characterized by extensive intraretinal hemorrhages and a variable degree of retinal ischemia. Macular edema is common, but intravitreal anti–vascular endothelial growth factor injections can provide significant and sustained visual improvement.[A18] Ischemic central vein occlusion is a major risk factor for developing secondary neovascular glaucoma.

Giant cell arteritis (temporal arteritis [Chapter 250]) can occlude the blood supply of the optic disc by inflammation of the short posterior ciliary arteries. This occlusion causes acute, painless loss of vision. Presenting symptoms before visual loss often include scalp tenderness or jaw claudication, which may be accompanied by weight loss and a vague sensation of fatigue. Diagnostic suspicion is further raised by an elevated erythrocyte sedimentation rate and/or C-reactive protein level. Temporal artery biopsy showing granulomatous inflammation in the region of the internal elastic lamina confirms the diagnosis. Because of the significant risk of visual loss in the initial and contralateral eye, even before laboratory or pathologic studies are known, systemic corticosteroid

therapy (e.g., oral prednisone 40 to 60 mg per day) should be administered for a protracted period until the sedimentation rate normalizes and symptoms are relieved (Chapter 250). Unfortunately, treatment usually does not restore lost vision in the presenting eye.

Nonarteritic ischemic optic neuropathy is caused by occlusion of the posterior ciliary arteries and infarction of the optic disc, resulting in acute, usually unilateral, painless loss of vision. There often are no antecedent symptoms except those systemic signs and symptoms associated with systemic nonarteritic vascular disease such as systemic hypertension. Occlusion is thought to be due to atherosclerosis or some other lumen-compromising mechanism. No treatment restores vision. There is a risk for the same process affecting the second eye.

IDIOPATHIC INFLAMMATORY AND AUTOIMMUNE DISORDERS

Ocular or periocular tissues may be the primary focus of isolated idiopathic or autoimmune inflammation. Pain is common, and changes in vision may occur.

KERATOCONJUNCTIVITIS SICCA

Keratoconjunctivitis sicca, or the dry eye syndrome, results from deficiency of any of the tear film layers. Symptoms include gritty, foreign body sensations, burning, photophobia, and decreased visual acuity. Idiopathic inflammation in keratoconjunctivitis sicca and xerostomia represents Sjögren syndrome (Chapter 247). Recurrent corneal erosion, keratitis, and corneal opacification can occur. Both systemic (e.g., β-blockers, α-agonists, antihistamines, anticholinergics) and topical (e.g., retinoids) medications can also cause dry eyes.

Artificial tears, up to four times daily, and lubricating ointments are helpful. Corticosteroids (e.g., loteprednol 0.5% eye-drops four times a day) are also effective as an initial treatment. Cyclosporine eye-drops (0.05%, one drop in each eye every 12 hours) are useful when other measures fail. In cases of severe tear deficiency, surgical closure of the lacrimal puncta may be performed to prevent drainage of tears into the nasal cavity.

SCLERITIS

Episcleritis, which is an inflammation immediately underlying the conjunctiva, is distinguished from conjunctivitis because its radially oriented vessels do not move with the conjunctiva. Mild pain may be present. Episcleritis is self-limited. Instillation of 10% phenylephrine is helpful in making the diagnosis because it causes blanching in episcleritis but not in scleritis. Oral or topical nonsteroidal anti-inflammatory medications such as flurbiprofen or diclofenac may hasten resolution.

Scleritis, which presents as severe pain and redness, is associated with infectious or autoimmune connective tissue disease in about 50% of cases. Vision may be reduced if the posterior sclera is involved. Diffuse or sectoral hyperemia is nonmobile and does not blanch with instillation of phenylephrine. Secondary uveitis and keratitis may occur. Diagnostic evaluation includes ultrasonography or magnetic resonance imaging and laboratory tests to identify potential underlying conditions. Treatment may require topical or oral nonsteroidal anti-inflammatory medications or corticosteroids.

MOOREN ULCER

Mooren ulcer is idiopathic, progressive, peripheral corneal thinning, likely autoimmune. It can be unilateral or bilateral, and pain is common. Topical corticosteroids, mucolytics, and cytotoxic agents have been used. Bandage contact lenses and conjunctival recession or advancement also have been used with variable success.

ORBITAL PSEUDOTUMOR

Nonspecific, idiopathic orbital inflammation involving the lacrimal gland (dacryoadenitis), extraocular muscles (myositis), orbital fat, sclera, or optic nerve sheath (optic perineuritis) can be caused by orbital pseudotumor. Some of the cases of idiopathic orbital inflammation have been recently associated with immunoglobulin G4 autoimmune disease. Pain is frequent. Patients may present with proptosis, limited ocular movements, or decreased acuity. Orbital ultrasonography or magnetic resonance imaging excludes a mass lesion. Patients respond dramatically to systemic corticosteroids within 24 hours, but the steroids must be tapered slowly over months to prevent recurrence.

IRITIS

Iritis presents with pain, photophobia, and blurred vision, with about 50% of cases related to systemic disease. Slit lamp examination shows inflammatory cells and protein exudate in the anterior chamber. Symptomatic treatment is with prednisolone acetate 1% suspension four times a day and cycloplegic drugs (cyclopentolate 1 or 2% twice daily) is usually effective, but repeated episodes require evaluation for autoimmune and infectious causes.

RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis (Chapter 243) is the most common specific childhood entity associated with uveitis. In adults, the ocular manifestations of rheumatoid arthritis mainly affect the anterior part of the eye, cornea, and sclera. Nearly 50% of patients who have peripheral ulcerative keratitis of the cornea have an associated systemic disease, mainly collagen vascular disease, and especially rheumatoid arthritis. Similarly, almost half of patients who have scleritis have an associated systemic disease, and about 15% of these are connective tissue diseases. Scleromalacia perforans, which is aseptic necrosis of the sclera, is associated with rheumatoid arthritis about 46% of the time.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (Chapter 245) causes eye manifestations from both the primary disease and its treatment with derivatives of chloroquine. Patients may have retinal vasculitis and can develop an ischemic or nonischemic optic neuritis, both of which can result in severe and permanent loss of vision. Hydroxychloroquine therapy can cause a toxic retinal degeneration, but this complication is rare during the first 10 years of use and lower at a dose of 5 mg/kg per day. Screening with visual fields or retinal imaging can detect toxicity before the patient complains of visual loss or any signs are seen on examination of the fundus.

SARCOIDOSIS

About 25% of patients with sarcoidosis (Chapter 83) develop chronic uveitis. Sarcoid also can involve the lids, conjunctiva, optic nerve, cranial nerves, and lacrimal glands. Anterior uveitis is treated topically with prednisolone acetate in decreasing doses, depending on degree of inflammation, and with daily cycloplegics (cyclopentolate 2%, atropine 1%). Posterior uveitis, dacryoadenitis, and neurologic manifestations require systemic corticosteroids, but the doses have not been standardized.

SYMPATHETIC OPHTHALMIA

Sympathetic ophthalmia is an autoimmune disease characterized by bilateral granulomatous uveitis following trauma to one eye. The condition is very rare, occurring in fewer than 1 per 10,000 cases of ocular surgical procedures and 1 per 1000 cases of accidental trauma.

The identified antigen within the eye is thought to be located in the outer retina. The disease is recognized clinically by signs of inflammation in the uninjured eye, generally 2 weeks or longer after the injury. Generally, removal of the injured eye within these 2 weeks will protect against the development of sympathetic ophthalmia in the uninjured eye, but once the uninjured eye is involved, removal of the originally injured eye is not likely to influence the process. Left untreated, inflammation may destroy the function of both eyes. When sympathetic ophthalmia is established, the patient will require anti-inflammation treatment (e.g., prednisolone, 1.0 to 1.5 mg/kg orally per day), most likely for an extended period. Most patients retain useful vision if treated at an early stage.

GENETICALLY DETERMINED DISEASES THAT MAY BECOME SYMPTOMATIC DURING ADULTHOOD

CORNEAL STROMAL DYSTROPHY

Most corneal dystrophies are autosomal dominant and bilateral, progress slowly, and primarily affect one layer of an otherwise normal cornea. Common types of dystrophies are anterior basement membrane, macular, granular, lattice, and Fuchs endothelial. Some result from mutations within the same gene. For example, the *BIGH3* on 5q31 is associated with granular and lattice dystrophy and corneal dystrophy of Bowman. The main symptom, caused by opaque corneal deposits, is blurred vision. If the decreased vision interferes with activities of normal living, a corneal transplantation can be performed.

CHOROIDAL DYSTROPHY

Choroidal dystrophies are progressive, inherited disorders characterized by atrophy of the retinal pigment epithelium and choroid. The main entities are central areolar choroidal sclerosis (autosomal dominant or recessive), gyrate atrophy (deficiency of the mitochondrial matrix enzyme ornithine-δ-aminotransferase), and choroideremia (deficiency of component A of Rab

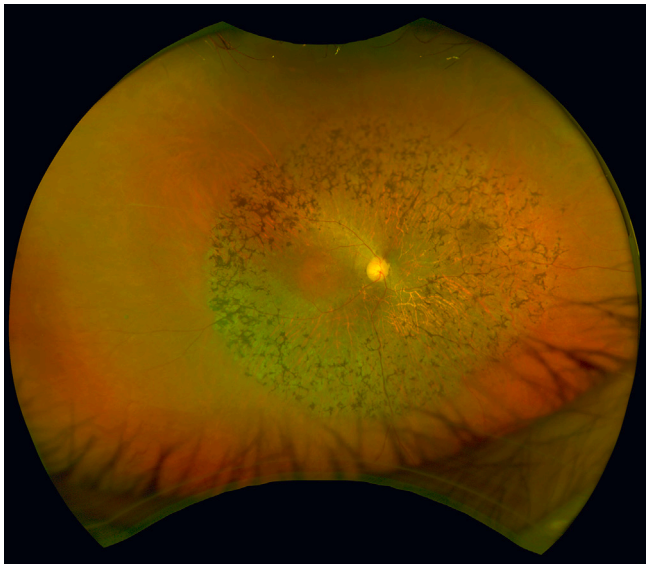

FIGURE 391-29. Retinitis pigmentosa. Fundus photograph shows "bone spicule" pigmentation of the midperipheral fundus, waxy pallor of the optic disc, and attenuated retinal vessels, the most consistent finding in retinitis pigmentosa.

geranylgeranyl transferase). No treatment exists for central areolar choroidal sclerosis or choroideremia. An arginine-restricted diet may be helpful in treating gyrate atrophy, and gene therapy trial has shown promising results for choroideremia. An arginine-restricted diet may also be helpful in treating gyrate atrophy.

RETINITIS PIGMENTOSA

Retinitis pigmentosa (Fig. 391-29) is bilateral and symmetrical, starts in early adult life, and is progressive. Retinitis pigmentosa can be an autosomal dominant or recessive disease, X-linked, digenic, mitochondrial, or sporadic. The primary defect, apoptotic in nature, appears to be in the neural retinal receptors. The main findings consist of the tetrad of bone-corpuscular retinal pigmentation; a pale, waxy optic nerve; attenuation of retinal arterioles; and a posterior subcapsular cataract. Night blindness is the primary symptom. The electroretinogram usually shows no electrical evidence of retinal function. Vitamin A palmitate supplementation (15,000 IU daily) may slow the rate of progression. Gene therapy is under investigation.

COMMON PEDIATRIC OR ADOLESCENT DISEASES THAT MAY PERSIST INTO ADULTHOOD

RETINOPATHY OF PREMATURITY

Retinal vascular development is not complete until 40 weeks of gestational age, so a premature infant is at risk of developing retinopathy of prematurity, in which blood vessels of the immature retina may leave the plane of the retina and grow into the adjacent vitreous body. The resulting tractional forces can cause total, irreversible retinal detachment and, ultimately, blindness. Myopia, strabismus, and amblyopia also are sequelae of retinopathy of prematurity. The primary risk factors for retinopathy of prematurity are early gestational age, low birth weight, and the use of supplemental oxygen. Early recognition and treatment (typically with laser photocoagulation) of retinal neovascularization are essential to halt progressive disease and prevent blindness.

HEMANGIOMA OF THE EYELID

Hemangioma of the eyelid is a hamartomatous (tissue normally found in the area) malformation of vessels in the soft tissues of the eyelid. The abnormal vascular lesion is usually insignificant at birth but grows in size over the first several months of life. The expanding hemangioma may cause astigmatism or mechanical ptosis, placing the infant at risk of amblyopia. The lesions rarely grow beyond 1 year of age and typically involute over time. If hemangiomas are small and not visually significant, observation is appropriate. Oral propranolol (1.5 to 3 mg/kg per day in two divided doses for up to 1 year), which is the treatment of choice for larger lesions or those at risk of causing amblyopia, can result in complete regression of the hemangioma.

CONGENITAL CATARACT

Congenital cataracts, which can be inherited as an autosomal dominant trait, are opacifications of the crystalline lens at birth. In congenital rubella (Chapter 339), the opacity is relatively limited to the fetal nucleus and has a pearl-like appearance. The cataract of galactosemia (Chapter 189) is potentially reversible with dietary restriction of galactose. Small cataracts can be observed, whereas dense cataracts that obstruct vision should be excised at an early age to prevent amblyopia.

TUMORS OF THE EYE

RETINOBLASTOMA

Retinoblastoma, the most common intraocular malignant tumor of childhood, results from uncontrolled proliferation of retinoblasts, which are pluripotential neuroectodermal cells that will differentiate into the various components of mature retina. A genetic deletion of the *Rb* (retinoblastoma) gene occurs in the chromosomal region 13q14. The tumor initially proliferates in the plane of the retina but is capable of involving all structures within the eye. Retinoblastoma may spread to the central nervous system through the optic nerve and vasculature to tissues at distant sites.

Approximately 40% of cases of retinoblastoma are heritable germline tumors generally diagnosed before the age of 12 months. In 80% of heritable retinoblastomas, tumors are bilateral and multiple in each eye. These patients also have a significant risk for developing a secondary primary malignant tumor (e.g., osteogenic sarcoma).

The nonheritable sporadic retinoblastomas arise spontaneously and represent about 60% of cases. The average age at presentation is 24 months, and patients generally have only a single tumor in one eye. Except in patients with mosaicism, the absence of germline mutations means that the risk for retinoblastoma in succeeding generations is low and the risk for a second primary tumor is the same as in the general population.

Retinoblastoma is often discovered by parents or relatives who notice a light reflex in one eye relative to the other either (white pupil or "cat's eye" reflex; leukocoria). Children with retinoblastoma also may present with strabismus, pseudocellulitis, iris neovascularization, dilated fixed pupil, secondary glaucoma, or tumor accumulation in the anterior chamber (neoplastic hypopyon). More advanced cases may present with signs of intraocular inflammation or ruptured globe with orbital extension. In some cases of spontaneously regressed retinoblastoma, the sole clinical sign may be a small, calcified tumor in the plane of the retina with surrounding retinal pigment epithelial scarring. Magnetic resonance imaging is the diagnostic test of choice.

Most children are treated with chemotherapy, sometimes with intraocular laser or cryotherapy. Enucleation is used for advanced cases in eyes with no visual potential.

MALIGNANT MELANOMA

Malignant melanoma (Chapter 188) of the conjunctiva is rare. Individuals at risk are middle aged and lightly pigmented. Melanoma of the conjunctiva arises most commonly from primary acquired melanosis but can occur as a de novo lesion and, rarely, from a preexisting conjunctival nevus. The regions of greatest risk are in the conjunctiva at the limbus (junction of cornea and sclera), in the conjunctival fornix (deep peripheral recesses of the conjunctiva), and in the caruncle (elevated nodule between the nasal lid margins). Extensions onto the corneal surface or formation of a nodule or loss of pigmentation are indications for excisional biopsy. Proliferation and hyperpigmentation of melanocytes without nuclear or cellular atypia is not associated with progression to melanoma, whereas associated nuclear or cellular atypia, particularly coupled with mitotic activity, is highly linked with progression to melanoma. Frank melanoma with a thickness of more than 0.8 mm is a risk factor for metastatic melanoma. Treatment is surgical excision, often supplemented with cryoablation. The long-term outcome is less favorable than for cutaneous melanoma because the tumor may metastasize early when the primary tumor is very small (e.g., 2 mm).

Malignant melanoma of the uveal tract[18] is the most common primary intraocular malignancy of adults, but its incidence is only 2 to 6 per 1 million per year in high-risk populations (blue-eyed, light-skinned persons). The tumor, which arises from preexisting nevi or dendritic melanocytes anywhere in the uveal tract, is almost always unilateral, unicentric, and nodular and is usually diagnosed at an asymptomatic phase during routine screening examination of the dilated fundus. Symptomatic tumors arise near sensitive portions of the retina (e.g., the macula) or cause retinal detachment or cystoid macular edema. Iris tumors (Fig. 391-30) are generally pigmented and elevated above the surrounding contour, where they are recognized early in their course.

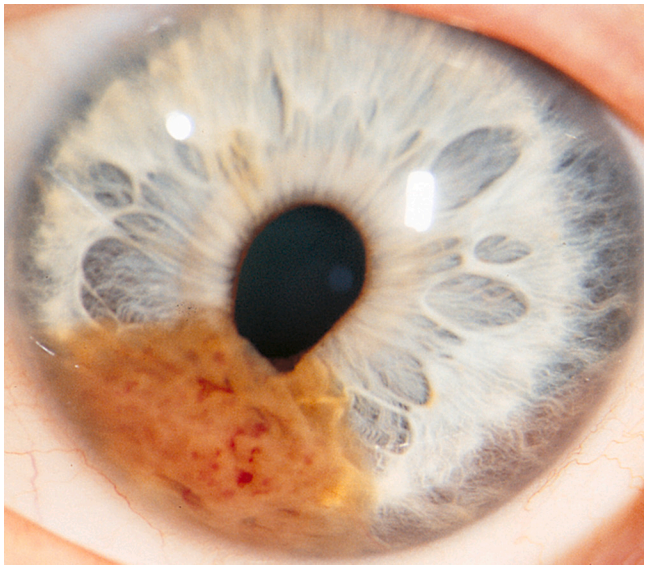

FIGURE 391-30. **Iris melanoma that has prominent intrinsic blood vessels. Note peaking of the pupil toward the tumor. (From Yanoff M, Duker JS, eds. *Ophthalmology*. Philadelphia: Mosby Elsevier; 2009.)**

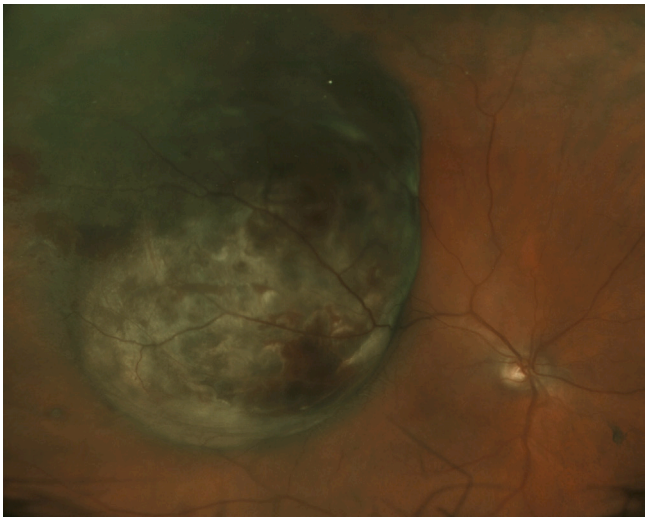

FIGURE 391-31. **Posterior choroidal melanoma.**

Posterior tumors, which originate under the retina, may extend into the vitreous cavity, be completely amelanotic, and occasionally may have a bilobed appearance (Fig. 391-31). Accuracy in diagnosing melanoma of the uveal tract by clinical means alone is greater than 98%. Treatment is controversial; options include enucleation of the eye, proton beam and plaque (iodine-125) radiation,[19] thermal laser ablation, photodynamic therapy, and en bloc resection. For metastatic uveal melanoma, intravenous tebentafusp (a bispecific protein with a T-cell receptor fused to an anti-CD3 effector at 20 μg on day 1, 30 μg on day 8, and 68 μg on day 15 and weekly thereafter) can significantly prolong survival.[A19] The survival rate can be as low as 50% at 15 years for large lesions. Risk factors for metastasis, most commonly to the liver, include tumor size, cell type, angiogenic mimicry, the presence of monosomy 3, and other genetic markers.

ORBITAL TUMORS

Primary tumors in the orbit of adults include cavernous hemangioma, schwannomas, and various proliferations of fibrous tissue (solitary fibrous tumor). Rhabdomyosarcoma may arise from ectopic rests of mesenchyme rather than from mature rectus muscle. Orbital tumors usually are diagnosed by imaging techniques. The treatment is orbital exploration and surgical removal.

LYMPHOMA

Orbital and conjunctival lymphomas are usually small (marginal zone B-cell lymphomas; Chapter 171). Approximately 50% of cases ultimately include systemic disease that may not be clinically diagnosed. External beam radiation is used to treat isolated periocular disease, whereas systemic chemotherapy (Chapter 171) is required for symptomatic, systemic involvement.

Large-cell B-cell lymphoma may present in the eye as a form of vitreitis (cells suspended in the vitreous) or a subretinal or intraretinal infiltrate before it is discovered in the central nervous system. The diagnosis may be verified by cytologic examination of vitrectomy specimens. Treatment is generally systemic (Chapter 171), but the outcome is usually poor.

The eye may infrequently be involved in multiple myeloma (Chapter 173). Retinal hemorrhages and vitreous opacification may occur. Periorbital osteolytic lesions of bone may be present.

TABLE 391-8 SYSTEMIC MEDICATIONS WITH OCULAR EFFECTS

AGENT	EFFECT
Chloroquine	Dyschromatopsia, visual field defects
Hydroxychloroquine	Dyschromatopsia, visual field defects; bull's-eye maculopathy
Thioridazine	Blurred vision
Chlorpromazine	Blurred vision
Digoxin	Yellow vision
Ethambutol	Optic neuritis
Amiodarone	Corneal whorls, pigmentary retinopathy
Corticosteroids	Glaucoma, cataract
Tamoxifen	Maculopathy
Neuroleptics	Nystagmus
Compazine	Oculogyric crisis
Vitamin A	Pseudotumor cerebri
5-Fluorouracil	Canalicular stenosis (tearing)
Isotretinoin	Severe dry eye (long-term effect)

LACRIMAL GLAND TUMORS

The lacrimal gland contains a resting population of non-nodal lymphocytes and is a common site for lymphomas. Epithelial neoplasms may arise from components of the acini and ducts of the lacrimal gland. Malignant epithelial tumors (adenoid cystic carcinoma) may metastasize at an early stage through perineural spaces of large peripheral nerves to adjacent bone. Most epithelial tumors are treated with total surgical removal of the lacrimal gland because of the risk for recurrence and malignant transformation of residual tumor. The prognosis for malignant lacrimal gland tumors is generally poor.

OCULAR METASTASIS

Metastasis to the orbit in adults is very uncommon because of its relatively small vascular volume. Metastasis to the rectus muscles present with adult-onset strabismus. Metastasis to the orbit is more common in childhood leukemia than adult leukemia.

Metastasis to the uveal tract is common, especially from primary breast and lung tumors. Metastatic lesions often grow rapidly and disturb visual function; serous retinal detachment is common. Treatment of the underlying malignancy can be effective on the choroidal lesions, but supplemental radiation or photodynamic therapy can be used to try to restore or preserve vision.

OCULAR EFFECTS OF SYSTEMIC MEDICATIONS

Innumerable medications may cause ocular side effects (Table 391-8). Therefore, patients taking systemic medications often require periodic surveillance to identify ocular toxicity.

The most common cause of drug-induced glaucoma is topical corticosteroid therapy of more than 4 to 6 weeks' duration in the 5 to 6% of the population who are genetically predisposed. Nonsteroidal drugs usually cause narrow-angle glaucoma. Sulfa-containing drugs may induce glaucoma as an idiosyncratic reaction in persons with either narrow or open anterior chamber configuration. Treatment is the same as for non–drug-induced glaucoma.

Chloroquine and *hydroxychloroquine* may cause decreased color vision and visual field defects at high doses. Chloroquine toxicity is thought to occur after a cumulative dose of 300 g, whereas hydroxychloroquine may cause symptoms after long-term maintenance of 750 mg/day. The macular portion of the fundus

develops a typical bull's-eye pattern of pigment disturbance. Corneal whorls composed of epithelial intracellular pigment may be seen. Vision loss from retinal toxicity is not reversible and tends to progress even after cessation of hydroxychloroquine treatment. Annual fundus examination with color testing, macular function tests, and automated visual field test may be indicated.

Ethambutol is often used for chronic pulmonary infection. The dose of drug is dependent on body weight. Toxic optic neuropathy is rare but unpredictable in incidence and outcome. Careful follow-up with close ophthalmic clinical surveillance is required.

Any of the commonly used antituberculous medications may cause optic neuropathy, although *ethambutol* carries the greatest risk. Pupillary response, color vision, acuity, and visual fields are the clinical parameters used to assess optic nerve function.

Cornea verticillata may be seen in patients taking *amiodarone* because of lysosomal accumulations within the epithelial basement membrane. *Fabry disease* produces similar changes, as can other medications. Corneal whorls are usually reversible when caused by drug toxicity, and they rarely interfere with vision.

392 NEURO-OPHTHALMOLOGY

ROBERT W. BALOH AND JOANNA C. JEN

A mechanistic understanding of vision impairment along with disturbances in pupillary and oculomotor control is often critical for diagnosing neurologic disorders. Although all physicians should be able to recognize neuro-ophthalmologic abnormalities,[1] precise diagnosis and treatment commonly requires specialty consultation.[2]

VISION

One of the most difficult diagnostic problems is vision loss that cannot be explained by obvious abnormalities of the eye. To evaluate such a patient properly, the examining physician must be familiar with the anatomy and physiology of the afferent visual system. The afferent visual pathways cross the major ascending sensory and descending motor systems of the cerebral hemispheres and in their anterior portion are intimately related to the vascular and bony structures at the base of the brain. Not surprisingly, localization of lesions within the afferent visual pathways has great value in neurologic diagnosis.

ANATOMY OF THE VISUAL PATHWAYS

Light entering the eye falls on the retinal rods and cones, which transduce the stimulus into neural impulses to be transmitted to the brain. The distribution of visual function across the retina takes a pattern of concentric zones increasing in sensitivity toward the center, the fovea. The fovea consists of a "rod-free" central grouping of approximately 100,000 slender cones. The ganglion cells subserving these cones send their axons directly to the temporal aspect of the optic disc, where they form the papillomacular bundle. Axons originating from ganglion cells in the temporal retina curve above and below the papillomacular bundle and form dense arcuate bands.

The arteries supplying the optic nerve and retina derive from branches of the ophthalmic artery. The central retinal artery approaches the eye along each optic nerve and pierces the inferior aspect of the dural sheath about 1 cm behind the globe to enter the center of the nerve. The artery emerges in the fundus at the center of the nerve head, from which it nourishes the inner two thirds of the retina by superior and inferior branches. Anastomotic branches derived from the choroidal and posterior ciliary arteries, the ciliary system, supply the choroid, optic nerve head, and outer retinal layers, including the photoreceptors. In about 10% of the population, the macula is supplied by a retinociliary artery, a branch of the ciliary system. Venous drainage from the retina and nerve head flows primarily through the central retinal vein, whose course of exit from the eye parallels that of entry of the artery.

What each eye "sees" is termed its *visual field* (Fig. 392-1). The nasal side of the left retina and the temporal side of the right see the left side of the world, and the upper half of each retina sees the lower half of the world. Behind the eyes, the optic nerves pass through the optic canal to form the optic chiasm. In the chiasm, nerves from the nasal half of each retina decussate and join the fibers from the temporal half of the contralateral retina. From the chiasm, the optic tracts pass around the cerebral peduncles to reach the lateral geniculate ganglia. The orientation of the visual field is rotated 90 degrees in the lateral geniculate such that images from the inferior visual field project to the medial half, whereas images from the superior visual field project to the lateral half. The geniculocalcarine radiation initially fans out into superolateral and inferolateral projections, the latter passing around the lateral ventricle and for a short distance into the temporal lobe (Meyer loop) before turning posteriorly to reach the striate cortex of the occipital lobe. In the occipital lobe, the striate cortex (area 17) lies along the superior and inferior bands of the calcarine fissure, with macular fibers projecting most posteriorly to the occipital pole and more peripheral retinal projections lying more anteriorly.

LOCALIZATION OF LESIONS WITHIN VISUAL PATHWAYS

Monocular vision loss is due to a lesion in one eye or optic nerve. Binocular visual loss, on the other hand, can result from disease located anywhere in

develops a typical bull's-eye pattern of pigment disturbance. Corneal whorls composed of epithelial intracellular pigment may be seen. Vision loss from retinal toxicity is not reversible and tends to progress even after cessation of hydroxychloroquine treatment. Annual fundus examination with color testing, macular function tests, and automated visual field test may be indicated.

Ethambutol is often used for chronic pulmonary infection. The dose of drug is dependent on body weight. Toxic optic neuropathy is rare but unpredictable in incidence and outcome. Careful follow-up with close ophthalmic clinical surveillance is required.

Any of the commonly used antituberculous medications may cause optic neuropathy, although *ethambutol* carries the greatest risk. Pupillary response, color vision, acuity, and visual fields are the clinical parameters used to assess optic nerve function.

Cornea verticillata may be seen in patients taking *amiodarone* because of lysosomal accumulations within the epithelial basement membrane. *Fabry disease* produces similar changes, as can other medications. Corneal whorls are usually reversible when caused by drug toxicity, and they rarely interfere with vision.

392 NEURO-OPHTHALMOLOGY

ROBERT W. BALOH AND JOANNA C. JEN

A mechanistic understanding of vision impairment along with disturbances in pupillary and oculomotor control is often critical for diagnosing neurologic disorders. Although all physicians should be able to recognize neuro-ophthalmologic abnormalities,[1] precise diagnosis and treatment commonly requires specialty consultation.[2]

VISION

One of the most difficult diagnostic problems is vision loss that cannot be explained by obvious abnormalities of the eye. To evaluate such a patient properly, the examining physician must be familiar with the anatomy and physiology of the afferent visual system. The afferent visual pathways cross the major ascending sensory and descending motor systems of the cerebral hemispheres and in their anterior portion are intimately related to the vascular and bony structures at the base of the brain. Not surprisingly, localization of lesions within the afferent visual pathways has great value in neurologic diagnosis.

ANATOMY OF THE VISUAL PATHWAYS

Light entering the eye falls on the retinal rods and cones, which transduce the stimulus into neural impulses to be transmitted to the brain. The distribution of visual function across the retina takes a pattern of concentric zones increasing in sensitivity toward the center, the fovea. The fovea consists of a "rod-free" central grouping of approximately 100,000 slender cones. The ganglion cells subserving these cones send their axons directly to the temporal aspect of the optic disc, where they form the papillomacular bundle. Axons originating from ganglion cells in the temporal retina curve above and below the papillomacular bundle and form dense arcuate bands.

The arteries supplying the optic nerve and retina derive from branches of the ophthalmic artery. The central retinal artery approaches the eye along each optic nerve and pierces the inferior aspect of the dural sheath about 1 cm behind the globe to enter the center of the nerve. The artery emerges in the fundus at the center of the nerve head, from which it nourishes the inner two thirds of the retina by superior and inferior branches. Anastomotic branches derived from the choroidal and posterior ciliary arteries, the ciliary system, supply the choroid, optic nerve head, and outer retinal layers, including the photoreceptors. In about 10% of the population, the macula is supplied by a retinociliary artery, a branch of the ciliary system. Venous drainage from the retina and nerve head flows primarily through the central retinal vein, whose course of exit from the eye parallels that of entry of the artery.

What each eye "sees" is termed its *visual field* (Fig. 392-1). The nasal side of the left retina and the temporal side of the right see the left side of the world, and the upper half of each retina sees the lower half of the world. Behind the eyes, the optic nerves pass through the optic canal to form the optic chiasm. In the chiasm, nerves from the nasal half of each retina decussate and join the fibers from the temporal half of the contralateral retina. From the chiasm, the optic tracts pass around the cerebral peduncles to reach the lateral geniculate ganglia. The orientation of the visual field is rotated 90 degrees in the lateral geniculate such that images from the inferior visual field project to the medial half, whereas images from the superior visual field project to the lateral half. The geniculocalcarine radiation initially fans out into superolateral and inferolateral projections, the latter passing around the lateral ventricle and for a short distance into the temporal lobe (Meyer loop) before turning posteriorly to reach the striate cortex of the occipital lobe. In the occipital lobe, the striate cortex (area 17) lies along the superior and inferior bands of the calcarine fissure, with macular fibers projecting most posteriorly to the occipital pole and more peripheral retinal projections lying more anteriorly.

LOCALIZATION OF LESIONS WITHIN VISUAL PATHWAYS

Monocular vision loss is due to a lesion in one eye or optic nerve. Binocular visual loss, on the other hand, can result from disease located anywhere in

ABSTRACT

Understanding neuro-ophthalmology is of great value in neurologic diagnosis. The afferent visual pathways cross the major ascending sensory and descending motor pathways of the cerebral cortex, and oculomotor control involves large parts of the cerebral cortex, cerebellum, and brain stem. The neuro-ophthalmologic examination requires a systematic assessment of both afferent and efferent pathways. Examination of the afferent system should include ophthalmoscopic visualization of the retina, visual acuity, visual fields, and pupillary responses. Examination of the efferent system should include assessment of the extraocular muscles, a search for ocular oscillations including nystagmus, and assessment of each of the supranuclear control systems—saccade, smooth pursuit, vergence, and vestibular.

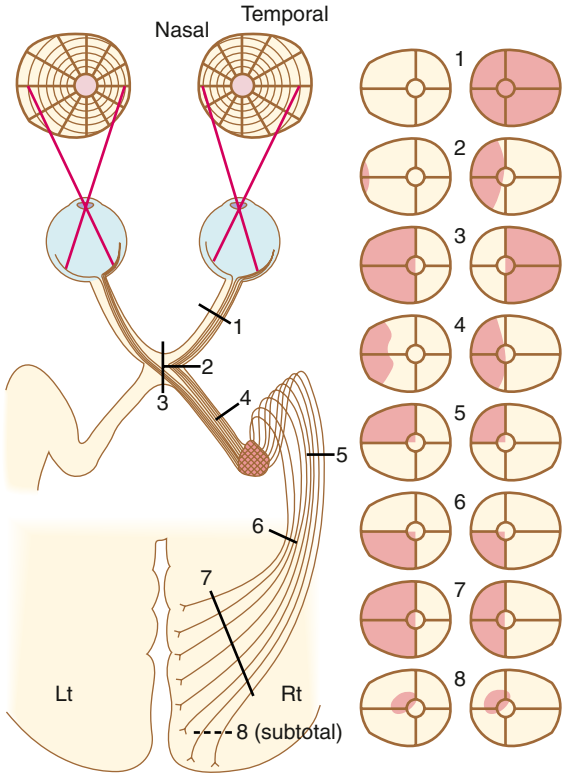

FIGURE 392-1. **Visual fields that accompany damage to the visual pathways.** *1*, Optic nerve: unilateral amaurosis. *2*, Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopia. *3*, Central optic chiasm: bitemporal hemianopia. *4*, Optic tract: incongruous, incomplete homonymous hemianopia. *5*, Temporal (Meyer) loop of the optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. *6*, Parietal (superior) projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. *7*, Complete parieto-occipital interruption of the optic radiation: complete congruous homonymous hemianopia with psychophysical shift of the foveal point, often sparing central vision and resulting in "macular sparing." *8*, Incomplete damage to the visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. Lt = left; Rt = right.

the visual pathways from the corneas to the occipital poles. Lesions involving the optic chiasm produce nonhomonymous visual abnormalities (e.g., the bitemporal hemianopia illustrated by lesion 3 in Fig. 392-1). Optic tract abnormalities are comparatively rare but produce characteristic visual changes. The fibers serving identical points in the homonymous half-fields do not fully commingle in the optic tract, so lesions damaging this structure produce incongruous homonymous hemianopia. Lesions of the geniculate nuclei, optic radiations, or visual cortex produce congruent hemianopic field defects that may go unrecognized unless the hemianopia intrudes on macular vision. Postgeniculate visual loss can be differentiated from pregeniculate visual loss by (1) a normal funduscopic appearance, (2) intact pupillary light reactions, and (3) appropriate lesions on brain imaging.

EXAMINATION OF THE AFFERENT VISUAL SYSTEM

Visual function is most commonly assessed by "best-corrected visual acuity" (Chapter 391). If visual acuity is not normal, it must be determined whether acuity can be improved with lenses or at least with the use of a pinhole. The normal reference is recognition of letters at an idealized 20 feet, and acuity charts are designed with even larger letters that are normally recognized at proportionally greater distances. Thus, if one reads letters at 20 feet no better than those normally perceived at 40 feet, vision is recorded as 20/40. Small visual charts that are easily carried in the physician's case permit quick and fairly accurate bedside appraisal of acuity.

Visual fields can be tested at the bedside by confrontation, and rough estimates of their integrity can be made even in patients with reduced alertness. The fields should be tested individually for each eye because the pattern of visual field defects can provide important localizing information. A quick screen of the visual fields can be made by having the patient fixate on the examiner's nose and identify the number of fingers flashed in each of the four visual field quadrants.

COMMON CAUSES OF VISUAL LOSS

Eye

The cause of monocular vision loss secondary to ocular and retinal lesions can often be detected by ophthalmoscopic examination or by measurement of intraocular pressure (Chapter 391). *Glaucoma* caused by impaired absorption of aqueous humor results in a high intraocular pressure that usually produces gradual loss of peripheral vision, "halos" seen around lights, and occasionally, pain and redness in the affected eye. *Retinal tears* and *detachments* give rise to unilateral distortions of the visual image seen as sudden angulations or curves of objects containing straight lines (metamorphopsia). *Hemorrhages* into the vitreous humor or infections or inflammatory lesions of the retina can produce scotomas that resemble those resulting from primary disease of the central visual pathway.

Binocular vision loss secondary to retinal disease in younger subjects is often due to *heredodegenerative conditions*. Vascular diseases, diabetes (Chapter 210), and age-related macular degeneration are causes in older patients. In most cases of *pigmentary retinal degeneration*, visual loss begins peripherally and slowly proceeds centrally. By contrast, *macular degeneration* (see Figs. 391-20 and 391-21) impairs central vision early in its course. A common variant in the complement factor H (*CFH*) gene is associated with a markedly increased risk for the development of age-related macular degeneration.

Optic Nerve

Acute or subacute monocular vision loss (Table 392-1) as a result of optic nerve disease is most commonly produced by demyelinating disorders, vascular obstruction, neoplasm, or hereditary optic neuropathy.[3] Demyelinating disease of the nerve head (*optic neuritis* or *papillitis*) produces disc edema along with loss of central vision in the affected eye only; subjectively unrecognized scotomas may sometimes be found in the other eye. Demyelination of the optic nerve behind the point where the retinal vein emerges (*retrobulbar neuritis*) initially leaves a normal-looking disc but a central or paracentral scotoma. With chronic demyelinating disorders, the optic disc becomes pale and atrophic.

Optic neuritis can be an isolated syndrome or a manifestation of systemic diseases.[4,5] The clinical course and therapeutic response of optic neuritis depend on the underlying inflammatory mechanism. In more than 50% of patients initially seen with optic neuritis, typical symptoms and signs of multiple sclerosis eventually develop (Chapter 380). Optic neuritis caused by multiple sclerosis is not responsive to steroids,[A1] but the underlying multiple sclerosis should be treated promptly. Some data suggest that phenytoin may be neuroprotective in patients with acute optic neuritis when used in doses of 4 to 6 mg/kg/day.[A2] Optic neuritis related to systemic lupus erythematosus (Chapter 245),[6] vasculitis (Chapter 249), or sarcoidosis (Chapter 83) may be steroid responsive.

Optic neuritis with an associated transverse myelitis is the clinical hallmark of *neuromyelitis optica*,[7] which is a severe demyelinating disease often mistaken for multiple sclerosis but now recognized to be caused by anti–aquaporin 4 autoantibodies. Standard treatment options include rituximab (1-g infusions at an interval of 2 weeks) or azathioprine (3 mg/kg/day orally). More recently, satralizumab (a humanized monoclonal antibody targeting the interleukin-6 receptor at 120 mg subcutaneously at 0, 2, and 4 weeks, then every 4 weeks thereafter), eculizumab (a terminal complement inhibitor at 900 mg intravenously weekly for 4 doses followed by 1200 mg every 2 weeks), and tocilizumab (an interleukin-6 receptor inhibitor at 8 mg intravenously every 4 weeks) have been shown to reduce the risk of relapse.[A3–A6] Doses should be adjusted based on response and immune suppression.[8]

Intraocular arterial occlusion may produce either central visual loss or an altitudinal field defect (*ischemic optic neuropathy*). Nonarteritic anterior ischemic optic neuropathy results from disease of the small vessels supplying the anterior portion of the optic nerve. The most common systemic disorders associated with it are hypertension (present in 50% of patients) and diabetes mellitus (present in 25%). Arteritic ischemic optic neuropathy is most commonly caused by giant cell arteritis (Chapters 63 and 250) and should be considered in all patients who are older than 50 years of age. Oral glucocorticoids are the cornerstone of treatment for giant cell arteritis but are not helpful in patients with nonarteritic anterior ischemic optic neuropathy.[A7]

Tumors (Chapter 175) invading the optic nerve or space-occupying lesions compressing it anywhere between the orbit and chiasm cause gradually decreasing central vision or a sector defect of the peripheral visual field. With such chronic lesions, the affected optic nerve becomes visibly atrophic.

Acute binocular vision loss resulting from bilateral optic nerve disease is most often caused by demyelinating disease or by toxic (methanol, tobacco, isoniazid) or nutritional factors (B vitamin deficiency, particularly of thiamine;

TABLE 392-1 COMMON CAUSES OF TRANSIENT MONOCULAR VISION LOSS

CATEGORY (TYPICAL DURATION)	CAUSES	DIFFERENTIAL FEATURES
Thromboembolism (1-5 min)	Atherosclerosis	Other atherosclerotic vascular disease, associated contralateral hemiparesis, angiography (carotid atheroma)
	Cardiac	Valvular disease, mural thrombi, atrial fibrillation, recent myocardial infarction
	Blood dyscrasia	Blood tests positive for sickle cell anemia, macroglobulinemia, multiple myeloma, polycythemia, other
Vasospasm (5-30 min)	Migraine	Ipsilateral headache, other classic aura, family history
Vascular compression (few seconds)	Increased intracranial pressure	Precipitated by position change, Valsalva maneuver, or pressure waves
	Tumor	Associated with slowly progressive monocular visual loss
Vasculitis (1-5 min)	Temporal arteritis	Associated with headache, polymyalgia rheumatica, palpable temporal artery, elevated sedimentation rate

TABLE 392-2 DIFFERENTIATION OF OPTIC NEURITIS FROM PAPILLEDEMA

	OPTIC NEURITIS	PAPILLEDEMA
Central-cecocentral vision loss	Present	Absent
Distribution	Usually unilateral	Usually bilateral
Ocular pain on movement	Present	Absent
Direct light reflex	±Reduced	Intact
CT and MRI of head	White matter plaques	Tumor, venous occlusion, etc.
Visual evoked responses	Abnormal	Normal
Lumbar puncture pressure	Normal	Elevated

CT = computed tomography; MRI = magnetic resonance imaging.

Chapter 384). In younger persons and those lacking a clear history of toxic exposure, demyelinating lesions overwhelmingly predominate. Symptoms are of abrupt or subacute onset with visual blurring, which may progress rapidly to blindness within hours or days. There may be pain about the eyes, particularly with movement. *Leber optic neuropathy*, caused by a mutation in mitochondrial DNA, typically begins painlessly and centrally in one eye, with the second eye affected weeks to months later. Gene therapy can modestly improve vision in both the treated and untreated eye,[A8] albeit only for 3 years or so.

Papilledema is disc edema secondary to increased intracranial pressure (Table 392-2). Vision is normal except under one of two circumstances: (1) acute transient episodes of amaurosis lasting a few seconds and attributable to acute increases in intracranial pressure (plateau waves); and (2) progressive loss of peripheral vision with long-standing, severe papilledema caused by compression of the optic nerve head. Idiopathic intracranial hypertension (Chapter 175)[9] is commonly seen in overweight women of childbearing age. Optical coherence tomography can help establish the diagnosis and differentiate papilledema from other optic disc abnormalities.[10] Subacute or chronic binocular vision loss secondary to optic nerve disease can result from *toxic* and *nutritional* causes or from *inherited optic atrophy*. Visual loss is painless and primarily affects central vision; ophthalmoscopy shows optic atrophy.

Chiasm and Optic Tract

Patients with lesions of the optic chiasm or optic tract are often unaware of visual impairment until the deficit encroaches on central vision in one or both eyes. Intrinsic or extrinsic neoplasms and parachiasmal arterial aneurysms are the most common lesions in this location. Gliomas that arise within the chiasm or optic tract are rare in adulthood. Extrinsic lesions compressing the chiasm or tract include *pituitary adenomas* (Chapter 205), *dysgerminomas, craniopharyngiomas, meningiomas* (Chapter 175), and large *aneurysms* of the carotid or basilar artery (Chapter 377). The diagnosis rests on finding the characteristic visual field abnormalities (bitemporal hemianopia for chiasm and incongruous homonymous hemianopia for optic tract lesions) and identifying the lesion with computed tomography or magnetic resonance imaging. Pituitary apoplexy secondary to acute hemorrhage into the gland (Chapter 205) can result in sudden vision loss; prompt neurosurgical intervention under steroid coverage is required for most patients.

Visual Radiations and Occipital Cortex

Lesions involving the postgeniculate visual pathways most often result from *vascular damage, traumatic injuries, neoplasms*, or rarely, *inflammatory* or *degenerative disorders* involving the cerebral white matter. Their localization can be deduced by the resulting visual field defects. Vascular disease of the occipital lobes is the most common cause of homonymous visual field defects in middle-aged and elderly people. *Anton syndrome* refers to cerebral visual loss with denial of a visual defect. Affected patients not only deny that they are blind but also confabulate details of their visual environment from memory. Anton syndrome results from bilateral lesions involving the parieto-occipital lobes or in the setting of metabolic encephalopathy. The reversible *posterior leukoencephalopathy syndrome*, which is characterized by headache, seizures, confusion, and cortical visual loss, is associated with an abrupt increase in blood pressure, such as may be seen with eclampsia and with immunosuppressive therapy after transplantation.

PUPILLARY CONTROL

The neuromechanisms that control pupil size and reactivity are complex, yet they can be evaluated by simple clinical procedures. The diameter of the pupil is determined by the antagonistic actions of the iris sphincter and dilator muscles, with the latter playing a minor role. If the sphincter muscle is severed or ruptured, it does not retract toward one quadrant but rather continues to function, except in the altered segment. Therefore, pupillary response can be evaluated even in the presence of significant damage to the iris.

ANATOMY AND LOCALIZATION OF LESIONS WITHIN PUPILLARY PATHWAYS

The size of the pupil is governed by tonic balance between sympathetic and parasympathetic innervation of the muscles of the iris. Sympathetic stimulation dilates the pupil, whereas parasympathetic stimulation constricts it. In the normal resting state, light entering the eye provides the major stimulus governing the size of the pupil (Fig. 392-2). Light activates the retinal rods and cones, with maximal sensitivity in the macular area. The optic nerve fibers follow the crossed and uncrossed visual pathways to the pregeniculate portion of the optic tracts, where the receptor fibers for light diverge to the pretectal nucleus located at the midbrain-diencephalic junction. Interneurons project from this nucleus to the Edinger-Westphal nuclei atop the midbrain third nerve nuclear complex of either side. From that point, paired parasympathetic efferents leave the midbrain in the third nerves, travel in the interpeduncular space across the petroclinoid ligament and edge of the tentorium, traverse the cavernous sinus, and then enter the orbit through the superior orbital fissure. In the orbit, the parasympathetic efferents synapse in the ciliary ganglion, from which ciliary nerves enter the eye to reach the pupillary muscles.

The principal sympathetic control of the pupil originates in the ventral lateral hypothalamus (first-order neuron), from which fibers descend ipsilaterally through the brain stem tegmentum and thence to the cervical cord, where they synapse with preganglionic neurons in the intermedial lateral column of the upper three thoracic segments. Preganglionic fibers (second-order neurons) emerge with the ventral roots of C8, T1, and T2 and ascend in the neck to synapse in the superior cervical ganglion adjacent to the base of the skull. Postganglionic (third-order neurons) pupillary fibers accompany the internal carotid artery through the skull and then leave it to follow the ophthalmic branch of the trigeminal nerve to reach the pupillodilator muscle of the eye.

EXAMINATION OF THE PUPIL

The pupillary response to light should be examined in a dimly lighted room, where the pupils are naturally dilated. First, the size and symmetry of the pupils are assessed by shining a dim light onto the face from below so that both pupils are seen simultaneously in the indirect illumination. To test light reactivity, gaze is directed at a distant object (so that constriction secondary to

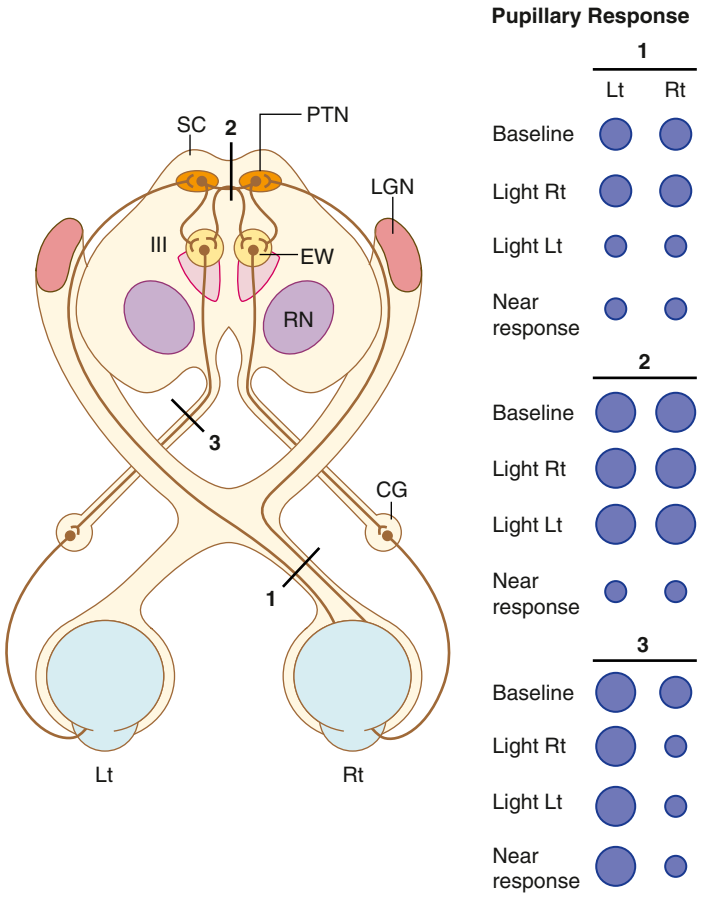

FIGURE 392-2. **Pupillary responses associated with lesions of the *(1)* optic nerve, *(2)* pretectum, and *(3)* oculomotor nerve.** Baseline is obtained with fixation on a distant target and the near response with a target in front of the nose. CG = ciliary ganglion; EW = Edinger-Westphal nucleus; LGN = lateral geniculate nucleus; Lt = left; PTN = pretectal nucleus; RN = red nucleus; Rt = right; SC = superior colliculus.

FIGURE 392-3. **Adie tonic pupil in the right eye of a young woman.** The affected pupil is "tonic"; that is, it responds slowly to light and accommodation but on rapid testing appears unresponsive. The site of the lesion is usually obscure, but the condition is benign. There may be associated areflexia. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

convergence is minimal), and first one and then the other pupil is illuminated with a bright light source. If a pupil reacts poorly to direct light, it is observed as the opposite eye is illuminated (consensual response). Pupils that react poorly to light should be tested for reactivity to the near reflex by first having the patient gaze at a distant object and then quickly fixate on an object just in front of his or her nose. *Light-near dissociation* refers to a pupil that does *not* react to light but does accommodate by constricting to a near target.

COMMON CAUSES OF PUPILLARY ABNORMALITIES

With so-called benign pupillary dilation, or *physiologic anisocoria*, a long-standing difference in the size of the two pupils is associated with normal reflex reactions; the disparity remains constant during constriction and dilation. Lesions compressing or damaging the pretectal region interrupt the afferent light reflex bilaterally to produce dilated and light-fixed pupils (e.g., lesion 2; see Fig. 392-2).[11] Pupillary constriction to the near response is preserved until late stages. Tumors of the pineal gland (e.g., dysgerminomas) and *localized infarctions* are the most common lesions in this location. *Adie tonic pupil* (Fig. 392-3) is a medium to large (3 to 6 mm) pupil that constricts little or not at all to light and very slowly to accommodation but constricts with the instillation of dilute (0.125%) pilocarpine (Fig. 392-4). The condition usually affects one eye (occasionally both), is more common in women 25 to 45 years of age, and carries no serious implications. It most likely results from postviral denervation of the pupillary muscles. Unexplained unilateral or bilateral dilated pupils as an isolated finding can result from *accidental or intentional instillation of mydriatic drugs*. Transdermal scopolamine is a common cause. Failure of the pupil to constrict promptly with pilocarpine (1%) gives the diagnosis if the history is unclear. Interruption of the emerging third nerve in the ventral midbrain or along the proximal part of its course produces a dilated pupil 6 to 7 mm in diameter. Important causes of compression of the third nerve in this region are *aneurysms* (Chapter 377), *neoplasia* (Chapter 175), and *brain herniation* (Chapter 175) as a result of increased intracranial pressure. In nearly all cases, the pupillary involvement is associated with other signs of third nerve involvement (see later text).

Sympathetic paralysis of the eye with ptosis, anhidrosis, and miosis (Horner syndrome; Fig. 392-5) can result from lesions anywhere along the pathway of the sympathetic innervation to the eye (Table 392-3). The diagnosis can sometimes be made by identifying associated signs in the brain stem or neck or along the carotid artery. *Argyll Robertson pupils* are small (1 to 2 mm), unequal, irregular, and fixed to light; they constrict minimally to accommodation. Their principal cause is tertiary neurosyphilis (Chapter 295).

OCULOMOTOR CONTROL

Abnormal eye movements can result from disturbances at several levels. Disconjugate eye movements result from lesions in the individual ocular muscles, the myoneural junctions, the oculomotor nerves and their three paired nuclei in the brain stem, and the internuclear medial longitudinal fasciculus (MLF), which yokes the eyes in horizontal movements. Supranuclear lesions typically produce disorders of conjugate gaze (gaze palsies).

ANATOMY AND LOCALIZATION OF LESIONS WITHIN THE OCULOMOTOR PATHWAYS

Nuclear and Internuclear Pathways

The abducens (sixth) nerve supplies the lateral rectus muscle. Selective involvement of the abducens nerve anywhere along its pathway leads to isolated weakness of abduction of the affected eye. Destruction of the abducens nucleus in the brain stem results in a conjugate gaze paralysis (ipsilateral) because, in addition to oculomotor neurons, the nucleus contains interneurons destined for the contralateral medial rectus nucleus. The trochlear (fourth) nerve supplies the contralateral superior oblique muscle, which turns in and depresses the eye. Patients with superior oblique weakness note an increase in diplopia with head tilt toward the side of weakness and often tilt their head in the opposite direction. At rest, there is slight upward deviation of the involved eye, and downward movement is impaired when the affected eye is turned in. Patients typically complain of diplopia when reading or going down stairs. The third (oculomotor) cranial nerve supplies the remaining ocular muscles. Involvement of the third nerve nucleus in the midbrain always produces at least some bilateral oculomotor weakness; the superior rectus division of the nucleus supplies the contralateral superior rectus muscle (all other divisions supply ipsilateral muscles). Peripheral third nerve paralysis can result from lesions damaging the structure anywhere from its course within the ventral midbrain to where it enters the orbit through the superior orbital fissure. When complete, third nerve palsy produces a widely dilated pupil, severe ptosis, and an externally deviated eye held in position by unopposed contraction of the lateral rectus muscle. In such conditions, the continued trochlear action reveals itself by intorsion of the eye when the subject attempts to look down.

The MLF interconnects the abducens nucleus in the pons with the contralateral oculomotor nuclear complex in the midbrain. It terminates cephalad in the interstitial nucleus in the rostral midbrain and can be traced as far caudad as the thoracocervical region of the spinal cord (coordinating nuchal-ocular control). Lesions involving the MLF characteristically produce internuclear ophthalmoplegia, in which the eyes are conjugate in the primary position but disconjugate on lateral gaze. With fully developed internuclear ophthalmoplegia on lateral gaze away from the side of the lesion, the contralateral eye abducts and shows nystagmus, whereas the ipsilateral adducting eye does not move

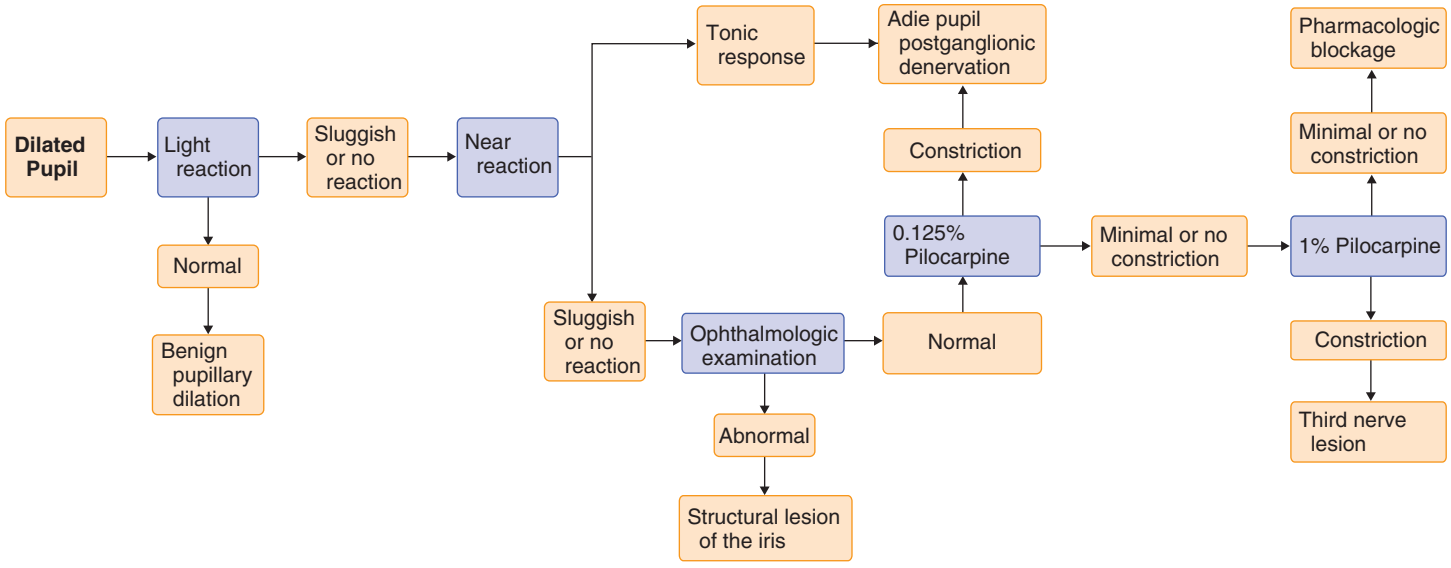

FIGURE 392-4. **Use of pilocarpine to help differentiate among different causes of a dilated pupil.**

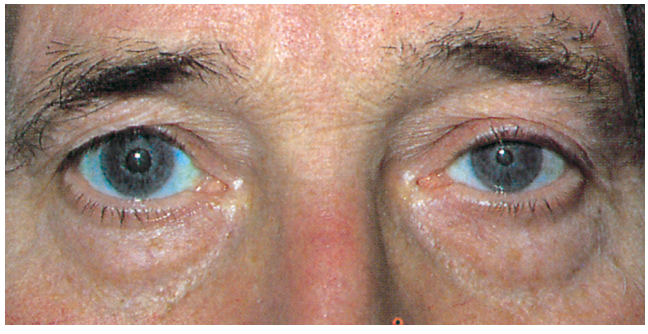

FIGURE 392-5. **Horner syndrome.** Note the characteristic ptosis of the left eye associated with constriction of the pupil (miosis). This patient had syringomyelia, but Horner syndrome has many possible causes. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

TABLE 392-3 HORNER SYNDROME RESULTS FROM LESIONS IN MULTIPLE LOCATIONS

LOCATION OF LESION	NEURON INVOLVED	TYPE OF LESION	ASSOCIATED SYMPTOMS AND SIGNS
Lateral brain stem	1st order	Infarction, glioma	Vertigo, nystagmus, imbalance, numbness, weakness
Apex of lung	2nd order	Lung cancer, trauma	Often none
Neck	3rd order	Carotid dissection or inflammation	Pain, monocular visual loss, hemiparesis

nasally because of failure of ascending impulses to reach the medial rectus division of the third nerve nucleus. Adduction for convergence is usually relatively maintained.

Supranuclear Pathways

Pathways descending from the frontal eye fields in the frontal lobe through the superior colliculi to the contralateral brain stem regulate rapid voluntary eye movements (*saccades*; E-Table 392-1).[12] Pathways descending from the parieto-occipital and frontal regions to the ipsilateral brain stem subserve slow visual tracking (smooth pursuit—foveal target; optokinetic—full-field target). For the vestibulo-ocular reflex, primary afferent neurons in the inner ear synapse with neurons in the vestibular nuclei, which in turn synapse with appropriate oculomotor neurons to produce compensatory eye movements. The *convergence* center is located in the rostral-dorsal midbrain near the vertical gaze center.

EXAMINATION OF EYE MOVEMENTS

Fixation and gaze holding are tested by having the patient look center, right, left, up, and down. Each position should be held steady and unwavering with the observer carefully documenting abnormal movements or ocular disconjugacies. Each supranuclear oculomotor control system is examined separately. *Saccades* are tested by having the patient alternately fixate on two targets such as the examiner's finger and nose; the speed and accuracy are noted. *Smooth pursuit* is tested by slowly moving a target back and forth and up and down and observing the patient's ability to produce smooth tracking movements. If the target velocity is low, normal subjects should be able to pursue without requiring catch-up saccades. The *vestibulo-ocular reflex* is evaluated with the head-thrust test (Chapter 396). *Convergence* is tested by having the patient follow a target moving from far to near. The degree of convergence depends to some extent on the cooperation of the patient. A clear sign that the patient is attempting to converge is simultaneous pupillary constriction.

COMMON CAUSES OF ABNORMAL OCULOMOTOR CONTROL

Strabismus (Ocular Misalignment)

A comitant (same in all directions of gaze) strabismus present since childhood is usually a benign *congenital disorder*. Latent congenital strabismus can become manifested in adulthood in association with a systemic illness. An acquired skew deviation (vertical displacement of the ocular axes) indicates a lesion within the otolith-ocular pathways (generally the brain stem). Incomitant strabismus can result from restrictive disease of the orbit or from abnormal muscle or oculomotor nerve function. The presence of mechanical restriction is confirmed by the use of forced duction testing (Fig. 392-6; after a topical anesthetic is applied to the eye, the ophthalmologist grasps the muscle insertion with large blunt-toothed forceps. Failure of the eye to deviate fully in the pulled direction implies restriction). Common causes of *orbital restrictive disease* include dysthyroid ophthalmopathy (Chapter 207), orbital pseudotumor, trauma, and orbital mass lesions (Chapter 391). Variable strabismus that increases with fatigue suggests *myasthenia gravis* (Chapter 390). A Tensilon test can usually confirm the diagnosis (see Fig. 392-6). If both restrictive disease and myasthenia gravis (Chapter 390) have been excluded, most patients with incomitant strabismus have processes affecting the oculomotor nuclei, their fascicles, or the cranial nerves themselves. Common causes of an *isolated third nerve palsy* in an adult include aneurysm (Chapter 377), small-vessel occlusive disease (including diabetes mellitus [Chapter 210]), trauma (Chapter 368), and neoplasm. Typically, third nerve lesions secondary to vascular disease spare the pupil. Vascular disease and trauma are by far the most common causes of *isolated trochlear nerve palsy*. The abducens nerve is particularly vulnerable to isolated traumatic involvement because of its long pathway outside the brain stem. Lesions that produce increased intracranial

E-TABLE 392-1 SUPRANUCLEAR OCULOMOTOR CONTROL SYSTEMS

SYSTEM	DESCRIPTION	FUNCTION	KEY ANATOMIC STRUCTURES
Saccade	Fast conjugate voluntary movements	Move the fovea to a new target of interest	Frontal eye field, superior colliculus, pretectum—vertical, pontine—horizontal cerebellar dentate nucleus
Smooth pursuit/ optokinetic	Slow conjugate tracking	Match eye velocity to target velocity	Occipital, parietal, pons, cerebellar flocculus
Vestibulo-ocular	Slow conjugate compensatory eye movements	Keep eyes stable when head moves	Pontomedullary region
Vergence	Slow disconjugate tracking	Focus on near and far targets	Pretectum, tectum

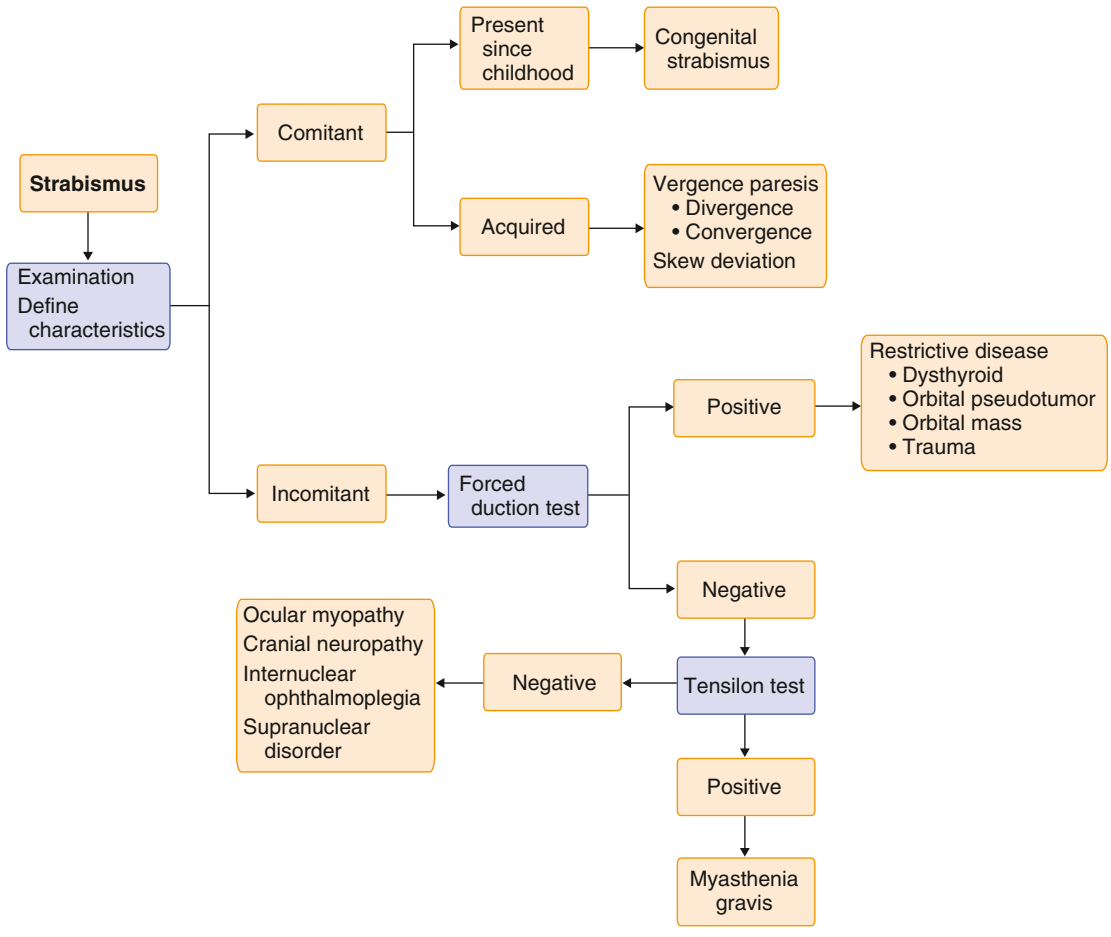

FIGURE 392-6. **Diagnostic tests that help differentiate among common causes of strabismus.**

pressure (Chapter 175) can lead to abducens nerve dysfunction regardless of the location and produce a "false localizing sign." Other common causes of *isolated sixth nerve palsy* are vascular disease (Chapter 376), trauma (Chapter 368), and neoplasm. Progressive external ophthalmoplegia, with worsening bilateral ptosis and diffuse reduction in ocular motility, is a manifestation of a mitochondrial myopathy.[13]

Internuclear Ophthalmoplegia

Internuclear ophthalmoplegia (Fig. 392-7) may be unilateral or bilateral, partial or complete, depending on the location of the lesion and the degree of damage to the MLF. *Demyelinating* and small *vascular lesions* are the most common causes of unilateral internuclear ophthalmoplegia unaccompanied by other ocular palsies or brain stem signs. Myasthenia gravis (Chapter 390) can produce an ophthalmoparesis resembling internuclear ophthalmoplegia as a result of greater involvement of the medial rectus than the lateral rectus. Demyelinating diseases (Chapter 380) are the most common causes of bilateral internuclear ophthalmoplegia involvement.

Disorders of Conjugate Gaze

Acute lesions involving a frontal eye field (e.g., hemorrhage or infarction [Chapters 376 and 377]) result in a transient inability to direct the eyes contralaterally. Vertical eye movements are not affected by unilateral lesions. Bilateral damage to the frontal eye fields or their descending pathways may produce an inability to move the eyes voluntarily (horizontally or vertically) despite preserved reflex eye movements, a condition called *oculomotor apraxia*. Lesions involving the horizontal gaze center in the pons produce an ipsilateral paralysis of conjugate gaze and tonic deviation of the eyes to the contralateral side (Chapter 391). Lesions of the pretectum selectively impair vertical gaze, with the vertical upgaze center being slightly rostral and dorsal to the vertical downgaze center. Patients with the *dorsal midbrain syndrome* (Parinaud syndrome) have a conjugate upgaze paresis. When they attempt to make upward saccades, convergence retraction nystagmus develops. As noted earlier, impaired convergence and light-near dissociation of the pupillary reflexes are also part of the syndrome. The most common causes of the dorsal midbrain syndrome include tumors of the pineal gland (Chapter 204; dysgerminomas), hydrocephalus (Chapter 175), and localized infarction.

Nystagmus

Spontaneous nystagmus can be congenital or acquired.[14] *Congenital nystagmus* typically has a high frequency and variable waveform (usually pendular) and is highly fixation dependent. It generally remains horizontal in all positions of gaze. The lifelong history and lack of symptoms confirm the diagnosis. Spontaneous nystagmus resulting from a *peripheral vestibular* lesion (i.e., in the labyrinth or vestibular nerve) usually has combined horizontal and torsional components (Table 392-4). The nystagmus resolves within a few days of the acute lesion. Acquired persistent spontaneous nystagmus indicates a lesion in the brain stem or cerebellum, or both. The latter is often purely vertical, horizontal, or torsional. Spontaneous *downbeat nystagmus*[15] is commonly seen with lesions of the cerebellum or cervicomedullary junction (e.g., Arnold-Chiari malformation [Chapter 385]).

Gaze-evoked nystagmus is always in the direction of gaze and is usually present with and without fixation. It is most commonly produced by the ingestion of *drugs* such as phenobarbital, phenytoin, alcohol, and diazepam (Chapter 96). It can also occur in patients with such varied conditions as myasthenia gravis (Chapter 390), multiple sclerosis (Chapter 380), and cerebellar atrophy. Asymmetrical horizontal gaze-evoked nystagmus is caused by a structural brain stem or cerebellar lesion (particularly at the cerebellopontine angle), with the lesion generally being on the side of the larger-amplitude nystagmus (Bruns nystagmus). *Rebound nystagmus* is a type of gaze-evoked nystagmus that either disappears or reverses direction as the eccentric gaze position is held. When the eyes are returned to the primary position, nystagmus occurs in the direction of the return saccade. Rebound nystagmus occurs in patients with cerebellar atrophy and focal structural lesions of the cerebellum; it is the only variety of nystagmus thought to be specific for cerebellar involvement. *Disconjugate gaze–evoked nystagmus* most commonly results from lesions of the MLF (see earlier discussion), but it can also occur with other lesions

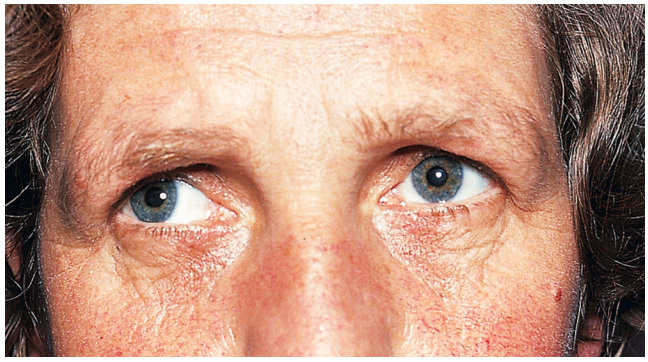

FIGURE 392-7. Internuclear ophthalmoplegia may be an initial feature of brain stem involvement in multiple sclerosis. On lateral gaze to the right, adduction of the left eye is incomplete. On convergence, eye movement was normal. The lesion is in the left medial longitudinal bundle, between the nucleus in the pons and the third nerve nucleus on the opposite side. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

TABLE 392-4 KEY DISTINGUISHING FEATURES OF PERIPHERAL AND CENTRAL TYPES OF SPONTANEOUS AND POSITIONAL NYSTAGMUS

TYPE OF NYSTAGMUS	PERIPHERAL (END ORGAN AND NERVE)	CENTRAL (BRAIN STEM AND CEREBELLUM)
Spontaneous	Unidirectional, fast phase away from the lesion, combined horizontal torsional, inhibited with fixation	Bidirectional or unidirectional; often pure horizontal, vertical, or torsional; *not* inhibited with fixation
Static positional	Fixed or changing direction, inhibited with fixation	Fixed or changing direction, *not* inhibited with fixation
Paroxysmal positional	Vertical-torsional, occasionally horizontal-torsional, vertigo prominent, fatigability, latency	Often pure vertical, vertigo less prominent, no latency, nonfatigable

of the brain stem involving the oculomotor nuclei. Positional nystagmus is discussed in Chapter 396.

Other Ocular Oscillations

Ocular bobbing consists of a fast conjugate downward eye movement followed by a slow return to the primary position. The phenomenon accompanies severe displacement or destruction of the pons or, less often, metabolic central nervous system depression. *Ocular myoclonus* consists of continuous rhythmic pendular oscillations, most often vertical, at a rate of one to three beats per second; it often accompanies palatal myoclonus and has a similar pathogenesis. *Square-wave jerks* and *ocular flutter* consist of brief, intermittent, horizontal oscillations (back-to-back saccades) arising from the primary gaze position. These types of ocular oscillation are most commonly seen with cerebellar disease but can also accompany more diffuse central nervous system disorders. *Opsoclonus* consists of rapid, chaotic, conjugate, repetitive saccadic eye movements (dancing eyes). Opsoclonus accompanies the cerebellar dysfunction, with the most chaotic varieties associated with brain stem encephalitis or the remote effects of systemic neoplasm, especially neuroblastoma in children. *Ocular dysmetria* refers to overshooting and undershooting of saccadic eye movements, often followed by multiple attempts at refixation. It reflects cerebellar dysfunction.

393 DISEASES OF THE MOUTH AND SALIVARY GLANDS

RICHARD C. JORDAN

More than 200 primary lesions or diseases occur in the oral mucosa, gingiva, teeth, jaws, and minor or major salivary glands. In addition, secondary abnormalities of the oral mucosa or salivary glands can be caused by systemic diseases or drugs. The most common or important of these diseases may be observed during physical examination.[1]

ORAL MUCOSAL DISEASES

ACUTE ULCERATIONS

Painful, short-lasting ulcerations can be caused by mechanical trauma, immunologic mechanisms, or bacterial or viral infections (Table 393-1). Soon after formation, oral mucosal ulcers become covered by a white to gray pseudomembrane, analogous to the yellow scabs on dry skin. Pseudomembrane-covered ulcers are distinguished from white hyperkeratotic lesions by their clinical features: pseudomembranes are removeable and painful, and they have a flat surface with an erythematous periphery. Traumatic ulcers are characteristically located on the tongue or inside the cheeks or lips close to the chewing surfaces of the teeth.

APHTHOUS STOMATITIS ("CANKER SORES")

These idiopathic recurrent ulcers are common, afflicting up to 20% of the population and can be found on nonkeratinized mucosa: the buccal mucosa, ventral tongue, lips, and alveolar mucosa (Fig. 393-1). They form well-defined, usually shallow, circular ulcers that may be single or multiple. There are three clinical forms: (1) minor, which are flat and less than 0.5 cm in diameter and last 5 to 10 days; (2) major, which have raised borders, are deeper, solitary, greater than 0.5 cm, and often last for weeks or months; and (3) herpetiform, which are usually clusters of very small ulcers that resemble recurrent herpetic lesions but are not preceded by vesicles and do not occur on keratinized mucosa. A viral or bacterial pathogenesis has not been established for any of these forms. Lesions clinically indistinguishable from minor aphthae occur in Behçet syndrome (Chapter 249). Aphthae are rarely associated with anemias or gluten-sensitive enteropathy (Chapter 126) and may become more frequent and severe in association with human immunodeficiency virus (HIV) infection (Table 393-2).

Minor or herpetiform aphthous ulcers are generally self-limiting within a week or two and may not require treatment unless they occur frequently.[2] Topical steroids, such as fluocinonide gel or ointment, can reduce the severity and duration of the lesions only if applied with prodromal symptoms or earliest signs. A freshly prepared suspension of tetracycline or doxycycline in water used as a mouth rinse at the onset of symptoms also reduces the severity and duration of disease.[A1] Unfortunately, none of these treatments prevent recurrent ulcers. Major aphthae usually require treatment with prednisone (e.g., 40 mg daily for 3 days); failure to respond significantly should prompt incisional biopsy to exclude neoplasia. Unfortunately, no treatment will cure a patient of recurrent aphthous stomatitis.[A2] Laser therapy may promote healing and pain relief in patients with recurrent aphthous stomatitis, although this approach has not been proven in clinical trials.

Other Ocular Oscillations

Ocular bobbing consists of a fast conjugate downward eye movement followed by a slow return to the primary position. The phenomenon accompanies severe displacement or destruction of the pons or, less often, metabolic central nervous system depression. *Ocular myoclonus* consists of continuous rhythmic pendular oscillations, most often vertical, at a rate of one to three beats per second; it often accompanies palatal myoclonus and has a similar pathogenesis. *Square-wave jerks* and *ocular flutter* consist of brief, intermittent, horizontal oscillations (back-to-back saccades) arising from the primary gaze position. These types of ocular oscillation are most commonly seen with cerebellar disease but can also accompany more diffuse central nervous system disorders. *Opsoclonus* consists of rapid, chaotic, conjugate, repetitive saccadic eye movements (dancing eyes). Opsoclonus accompanies the cerebellar dysfunction, with the most chaotic varieties associated with brain stem encephalitis or the remote effects of systemic neoplasm, especially neuroblastoma in children. *Ocular dysmetria* refers to overshooting and undershooting of saccadic eye movements, often followed by multiple attempts at refixation. It reflects cerebellar dysfunction.

393 DISEASES OF THE MOUTH AND SALIVARY GLANDS

RICHARD C. JORDAN

More than 200 primary lesions or diseases occur in the oral mucosa, gingiva, teeth, jaws, and minor or major salivary glands. In addition, secondary abnormalities of the oral mucosa or salivary glands can be caused by systemic diseases or drugs. The most common or important of these diseases may be observed during physical examination.[1]

ORAL MUCOSAL DISEASES

ACUTE ULCERATIONS

Painful, short-lasting ulcerations can be caused by mechanical trauma, immunologic mechanisms, or bacterial or viral infections (Table 393-1). Soon after formation, oral mucosal ulcers become covered by a white to gray pseudomembrane, analogous to the yellow scabs on dry skin. Pseudomembrane-covered ulcers are distinguished from white hyperkeratotic lesions by their clinical features: pseudomembranes are removeable and painful, and they have a flat surface with an erythematous periphery. Traumatic ulcers are characteristically located on the tongue or inside the cheeks or lips close to the chewing surfaces of the teeth.

APHTHOUS STOMATITIS ("CANKER SORES")

These idiopathic recurrent ulcers are common, afflicting up to 20% of the population and can be found on nonkeratinized mucosa: the buccal mucosa, ventral tongue, lips, and alveolar mucosa (Fig. 393-1). They form well-defined, usually shallow, circular ulcers that may be single or multiple. There are three clinical forms: (1) minor, which are flat and less than 0.5 cm in diameter and last 5 to 10 days; (2) major, which have raised borders, are deeper, solitary, greater than 0.5 cm, and often last for weeks or months; and (3) herpetiform, which are usually clusters of very small ulcers that resemble recurrent herpetic lesions but are not preceded by vesicles and do not occur on keratinized mucosa. A viral or bacterial pathogenesis has not been established for any of these forms. Lesions clinically indistinguishable from minor aphthae occur in Behçet syndrome (Chapter 249). Aphthae are rarely associated with anemias or gluten-sensitive enteropathy (Chapter 126) and may become more frequent and severe in association with human immunodeficiency virus (HIV) infection (Table 393-2).

Minor or herpetiform aphthous ulcers are generally self-limiting within a week or two and may not require treatment unless they occur frequently.[2] Topical steroids, such as fluocinonide gel or ointment, can reduce the severity and duration of the lesions only if applied with prodromal symptoms or earliest signs. A freshly prepared suspension of tetracycline or doxycycline in water used as a mouth rinse at the onset of symptoms also reduces the severity and duration of disease.[A1] Unfortunately, none of these treatments prevent recurrent ulcers. Major aphthae usually require treatment with prednisone (e.g., 40 mg daily for 3 days); failure to respond significantly should prompt incisional biopsy to exclude neoplasia. Unfortunately, no treatment will cure a patient of recurrent aphthous stomatitis.[A2] Laser therapy may promote healing and pain relief in patients with recurrent aphthous stomatitis, although this approach has not been proven in clinical trials.

ABSTRACT

More than 200 primary lesions or diseases occur in the oral mucosa, gingiva, teeth, jaws, and minor or major salivary glands. In addition, secondary abnormalities of the oral mucosa or salivary glands can be caused by systemic diseases or drugs. The most common or important of these diseases may be observed during physical examination.

TABLE 393-1 ORAL MUCOSAL ULCERS

TYPE/DISEASE	CLINICAL FEATURES
INSIDIOUS ONSET, CHRONIC	
Multiple or Bilateral	*Shallow ulcers on mucosa, skin, or both*
Pemphigus vulgaris	Begin as fragile, short-duration blisters
Mucous membrane pemphigoid	Begin as short-duration blisters
Lichen planus	Bilaterally symmetrical lesions (white lacelike with or without erythema)
Lupus erythematosus	Asymmetrical lesions, with or without systemic lupus (white with or without erythema)
Lichenoid drug reaction	Variable lesions; often unilateral; history of medication use
Epidermolysis bullosa	Begin as blisters; lifelong history
Solitary	*Indurated or cratered ulcers*
Squamous cell carcinoma	Most common on tongue, oropharynx, lip, mouth floor
Adenocarcinomas, various	Salivary tumors most common; on palate, cheeks, mouth floor
Tuberculosis	Usually painful
Actinomycosis	Often associated with draining sinus tract
Deep mycoses (particularly histoplasmosis, coccidioidomycosis)	Associated with systemic infection; can resemble carcinoma clinically
Midline (lethal) granuloma	Associated with necrosis, may perforate palate; usually an NK/T-cell lymphoma or granulomatosis with polyangiitis
Bony osteonecrosis	Associated with prior cancer, radiation therapy or bisphosphonate/antiresorptive agent use
ACUTE ONSET, OFTEN SELF-LIMITING	
Clusters	*Usually small and shallow ulcers; history of blisters*
Primary herpes simplex	Any oral mucosal site, associated with fever, malaise; often widespread
Recurrent herpes simplex	Unilateral, only on keratinized mucosa (gingiva, hard palate, or lip)
Varicella-zoster	Unilateral lesions along neural distribution
Herpangina	Usually bilateral on soft palate
Measles (rubeola)	Precede skin rash; associated with fever, malaise
Solitary or Multiple (without Clustering)	*Variable, usually without history of blisters*
Traumatic ulcers	Usually solitary; history of trauma
Aphthous stomatitis (canker sores)	Circular, often multiple, shallow, only on nonkeratinized mucosa
Behçet syndrome	Oral lesions similar to recurrent aphthae
Erythema multiforme	Multiple lesions, often involve lower labial mucosa with hemorrhagic crust
Drug reaction	Appropriate history of drug use
Necrotizing sialometaplasia	Deep ulcers, usually on palate; can be associated with trauma
Primary syphilis	Solitary, indurated, painless, any site
Gonorrhea	Painful, surrounded by erythema, usually in oropharynx

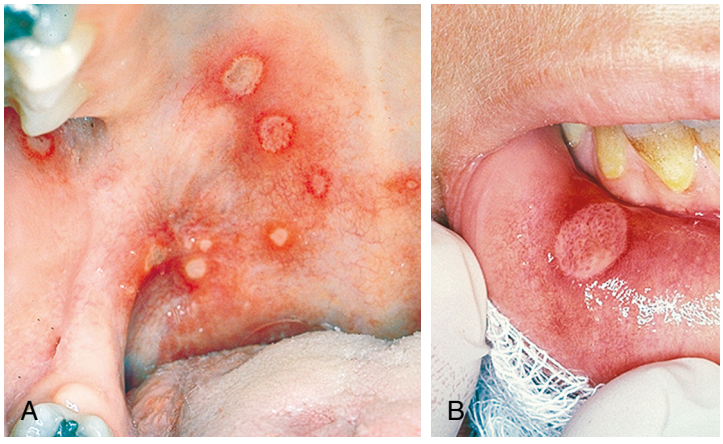

FIGURE 393-1. Aphthous ulcers. A, A cluster of minor aphthae on the soft palate and buccal mucosa, present about 1 week. **B,** A major aphthous ulcer on the labial mucosa, present about 3 weeks.

TABLE 393-2 ORAL LESIONS ASSOCIATED WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Kaposi sarcoma (human herpesvirus type 8)
Candidiasis (pseudomembranous, hyperplastic, and/or erythematous lesions)
Other opportunistic fungal infections (e.g., histoplasmosis or coccidioidomycosis)
Aphthous ulcers (increased frequency, duration, or size)
Virus-associated epithelial hyperplasias Hairy leukoplakia (Epstein-Barr virus) Oral wart (human papillomavirus type 6, 11, and other types) Focal (multifocal) epithelial hyperplasia (Heck disease) (human papillomavirus types 13 and 32) Condyloma acuminatum (human papillomavirus types 6 and 11)
Herpes zoster (varicella-zoster virus)
Exaggerated forms of gingivitis and inflammatory periodontal disease
Decreased salivary gland function
Parotid gland enlargement (lymphoepithelial lesion)
Non-Hodgkin lymphoma (e.g., plasmablastic lymphoma)

VIRAL ULCERS

Several types of virus (most commonly herpes simplex type 1; Chapter 345) cause multiple oral mucosal vesicles that last only a few hours or days and then become irregular shallow ulcers. In the initial infection by herpes simplex virus, usually in children, numerous vesicles may appear on any oral mucosal site (called primary herpetic gingivostomatitis), accompanied by malaise, headache, fever, and cervical lymphadenopathy. Patients previously exposed to this virus may develop recurrent (secondary) lesions that appear as clusters of small vesicles, most commonly on the lips (herpes labialis) and less commonly on the keratinized mucosa of the gingiva or hard palate (Fig. 393-2). Such lesions contain live virus and tend to recur at the same site but less frequently with increasing age.

Although widespread vaccination has reduced the incidence, similar mucosal vesicles may also accompany the initial infection by the varicella-zoster virus in children with chickenpox (Chapter 346), and unilateral lesions may occur if herpes zoster (Chapter 346) affects branches of the trigeminal nerve. Uncommonly, oral mucosal ulcers may be caused by different types of coxsackievirus (Chapter 349), appearing on any oral site in hand-foot-and-mouth disease or on the soft palate or pharynx in herpangina. After infection by the measles (rubeola) virus, small ulcers (Koplik spots; see Fig. 338-2 in Chapter 338) may form on the inside of the cheeks 1 to 2 days before development of the skin rash (Chapter 338). Patients with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Chapter 336) may have a variety of oral manifestations, including erosions, ulcers, bullae, vesicles, and pustules.[3]

MUCOSITIS ASSOCIATED WITH CANCER TREATMENT

Patients who receive radiation therapy for cancers where the radiation fields include the oral cavity are at risk for the development of oral mucositis (Chapters 18 and 176). Oral mucositis is also common in patients who receive intensive chemotherapy for malignancies, such as patients who have leukemia (Chapters 168 to 170) or undergo hematopoietic stem cell transplantation (Chapter 163). Oral mucositis also occurs in about 20 to 40% of patients treated with chemotherapy for other solid tumors. Risk factors include smoking, poor oral hygiene, a lower pretreatment neutrophil count, and the depth of treatment-induced neutropenia. Agents with higher risks include anti-angiogenic tyrosine kinase inhibitors (e.g., axitinib, cabozantinib, pazopanib, sorafenib, and sunitinib) and mammalian target of rapamycin (mTOR) inhibitors (e.g., everolimus), as well as etoposide, fluorouracil, and methotrexate. The pathobiology is cytotoxic damage to rapidly dividing cells, predominantly basal cells of the mucosal epithelium, by chemotherapy and radiation.

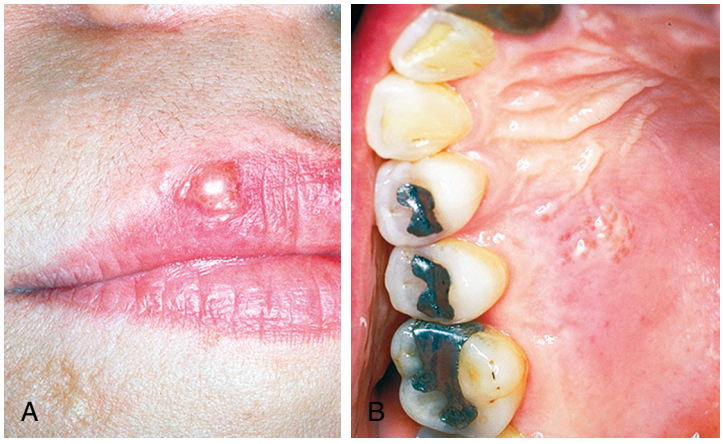

FIGURE 393-2. Clusters of recurrent herpes simplex vesicles. A, On the lip; B, on the hard palate, both present 2 to 3 days, in different patients.

Patients can develop pain and sensitivity to irritating substances, which can be avoided by the patient. Mild mucositis may be difficult to confirm on examination, but oral ulceration is the hallmark of the condition. Bleeding occurs with more severe mucositis. A complete blood count with differential is helpful, and the patient should also be assessed for any signs of dehydration (Chapter 7).

For patients with mild symptoms, a bland mouthrinse (e.g., normal saline or sodium bicarbonate in water) as a "swish and spit" can be symptomatically helpful. For moderate pain that does not interfere with oral intake, patients should avoid hard-consistency, rough, or sharp foods; alcohol; and smoking. A 2% oral lidocaine solution can be added to a normal saline or sodium bicarbonate mouthrinse. For more severe mucositis, topical agents include a doxepin mouthrinse and "Magic" mouthwashes. For more severe pain that interferes with eating, dehydration, neutropenia, or suspected systemic infection, expert consultation and typically hospitalization must be considered. For radiation-induced mucositis, a diphenhydramine/lidocaine/antacid mouthwash can reduce the incidence and severity of mucositis, and dexamethasone mouthwash can provide analogous benefits for patients receiving mTOR inhibitors.[4]

ERYTHEMA MULTIFORME

In this potentially recurrent disease, painful oral mucosal ulcerations develop rapidly, with or without target-like skin lesions. It may be associated with a previous viral infection or hypersensitivity to a food or drug. The affected patients, usually young adults with minimal or no systemic symptoms, have irregularly shaped ulcers that can be small and few or involve large areas of the mucosa; the most common sites are the lower labial mucosa and vermilion. On the vermilion of the lips, bilateral hemorrhagic crusting is a characteristic finding. These lesions can be distinguished from those of primary herpes by the absence of oral vesicles and systemic symptoms or by the presence of characteristic skin lesions (Chapter 406). A major variant of this disease is Stevens-Johnson syndrome, in which ocular, genital, and other lesions may accompany the oral lesions.

VENEREAL INFECTIONS

Primary syphilis may arise as a solitary, indurated, painless ulcer on the oral mucosa that resolves spontaneously in 4 to 6 weeks (Chapter 295). Uncommonly, *Neisseria gonorrhoeae* (Chapter 275) may cause oral ulcers, usually in the soft palate and pharynx, which may be confused with oral ulcers of other causes.

ORAL SQUAMOUS CELL CARCINOMA

About 4% of all cancers occur in the mouth, most commonly as squamous cell carcinomas of the mucosal epithelium (Chapter 176). Oral carcinoma occurs usually in the fifth decade or beyond, in men twice as frequently as in women, and is associated with long-term use of tobacco in more than 80% of cases.

Oral carcinoma usually arises as a chronic, indurated, cratered ulcer, but white (leukoplakia) and especially red (erythroplakia) macular lesions (Table 393-3; Fig. 393-3) frequently exhibit premalignant epithelial dysplasia or early carcinoma. Oral carcinomas spread to cervical lymph nodes. The overall 5-year survival rate is about 50%, but early treatment of small, localized lesions can lead to survival rates as high as 90%. Nevertheless, current guidelines find insufficient evidence to recommend for or against screening in asymptomatic adults.

TABLE 393-3 WHITE AND RED/BLUE ORAL MUCOSAL LESIONS

WHITE LESIONS (PLAQUES)
Squamous cell carcinoma (early)
Frictional keratosis (buccal mucosa at dental occlusal line)
Leukoplakia (with or without dysplasia)
Smokeless tobacco–associated lesions
Nicotine stomatitis (palate)
Lichen planus (reticular and plaque types)
Pseudomembranous candidiasis (thrush)
Hyperplastic candidiasis (candidal leukoplakia)
Hairy leukoplakia (immunosuppression related, often with HIV infection; usually on lateral tongue)
Geographic tongue (benign migratory glossitis)
Mucous patch or condyloma latum of secondary syphilis
Pseudomembrane-covered ulcers (see Table 393-1)
RED OR BLUE LESIONS (MACULAR, MACULOPAPULAR)
Squamous cell carcinoma (early)
Erythroplakia (epithelial dysplasia)
Erythematous (atrophic) candidiasis
Median rhomboid glossitis
Mucocutaneous diseases (see Table 393-1)
Angular cheilitis
Telangiectasias and purpuras (red to blue)
Kaposi sarcoma (blue to purple)

HIV = human immunodeficiency virus.

FIGURE 393-3. Squamous cell carcinoma. Biopsy of this area of erythroplakia with slight induration in the anterior mouth floor exhibited squamous cell carcinoma.

Over the past two decades, there has been a rapid increase in a type of head and neck cancer associated with human papillomavirus (HPV) type 16 (Chapter 344).[5] Occurring primarily at the base of the tongue and tonsillar region of the oropharynx, this form of nonkeratinizing squamous cell carcinoma is seen in younger patients who typically lack the history of smoking and alcohol. Other features of the disease include advanced stage at presentation and its favorable response to radiation and chemotherapy (Chapter 176). In the absence of concurrent tobacco use, the 5-year survival rate is over 80%.

OTHER CHRONIC ULCERATIONS

Prescription drugs that can be responsible for chronic oral mucosal ulcerations include barbiturates, β-blockers, nonsteroidal anti-inflammatory drugs, allopurinol, isoniazid, and many others. Several mucocutaneous diseases can cause chronic multifocal oral mucosal lesions composed of ill-defined areas of erythema and ulceration. They are among the most difficult oral lesions to diagnose and are discussed later with the red lesions (see Table 393-3). Several microbial infections or underlying osteonecrosis (e.g., with the use of bisphosphonates and other antiresorptive medications) can lead to indurated, chronic oral mucosal ulcerations with moderate symptoms (see Table 393-1).

WHITE LESIONS

White plaques are commonly found in the mouth and, like ulcerations, have a wide variety of causes and outcomes (see Table 393-3). The clinical descriptor term *leukoplakia* applies to a white plaque that does not rub off and whose appearance does not indicate another disease. Leukoplakia can occur in any

area of the mouth and usually exhibits benign hyperkeratosis on biopsy.[6] On long-term follow-up, 2 to 6% of these lesions undergo malignant transformation into squamous cell carcinoma. Leukoplakias that are shown on biopsy to contain epithelial dysplasia have a higher rate of transformation to cancer than those that do not, thereby emphasizing the important role of biopsy for these lesions. Areas of leukoplakia with a corrugated surface or mixed with areas of erythema are often found in the lower labial or buccal vestibule of patients who use smokeless tobacco.

Frictional keratoses are often found posterior to the lower molar teeth as irregular white plaques and on the buccal mucosa as white lines adjacent to the dental occlusion. Unlike leukoplakia, these lesions rarely become malignant.

LICHEN PLANUS

Oral lesions of lichen planus (Chapter 405) occur in about 1% of the population, usually as multiple, bilaterally symmetrical reticular (lattice-like) white lesions, with or without adjacent areas of erythema (atrophy or erosion) or irregular ulcers (Fig. 393-4). The presence of mucosal atrophy, erosion, or ulceration usually causes pain and sensitivity to certain foods. Most lesions can be adequately controlled by topical application of fluocinonide or clobetasol gel or ointment (0.05%, three times a day) for periods of several weeks,[A3] although recurrence is common.

ORAL CANDIDIASIS

This common fungal disease (Chapter 310) has three clinical forms: pseudomembranous (thrush), erythematous (atrophic), and hyperplastic (candidal leukoplakia).[7] Pseudomembranous candidiasis, usually of relatively short duration, occurs on any site and consists of white fungal plaques that can be rubbed off, leaving a red or bleeding base. Lesions of hyperplastic candidiasis are white, have fungal hyphae within the surface layers of hyperkeratotic epithelium, do not rub off, and are most often found on the anterior buccal mucosa or on the tongue. Erythematous candidiasis is discussed under Red Lesions. All forms of oral candidiasis represent overgrowth or superficial infection by *Candida* species from the oral flora, induced by a variety of causes, including suppression of bacterial flora by systemic antibiotics, chronic salivary dysfunction, uncontrolled diabetes mellitus or anemia, and immunosuppression (especially in HIV-infected patients). The condition can be managed with topical or systemic antifungal agents, although acquired resistance to fluconazole (discussed later) therapy can occur.

HAIRY LEUKOPLAKIA

The lesion of hairy leukoplakia, which is caused by Epstein-Barr virus, is a white plaque occurring most frequently on the lateral surfaces of the tongue bilaterally in immunosuppressed persons, usually but not always HIV infected (Fig. 393-5). Hairy leukoplakia also is purported to occur rarely in immunocompetent patients.[8] *Candida* may be present in the surface layers, but the lesion is not eliminated by effective antifungal therapy. The diagnosis of hairy leukoplakia by biopsy should raise suspicion of HIV infection or other forms of systemic or local immunosuppression.

GEOGRAPHIC TONGUE

Also called *benign migratory glossitis*, this common, benign, idiopathic condition affects the dorsal tongue of about 2% of the population. It is characterized by well-defined areas of atrophied filiform papillae bordered by arcs of normal or hyperplastic filiform papillae and by gradual changes in the location of these lesions over time (Fig. 393-6). Lesions that appear to be geographic tongue on other oral sites should prompt consideration of concurrent inflammatory bowel disease (Chapter 127). Treatment is usually ineffective and not necessary.

SECONDARY SYPHILIS

Secondary syphilis may manifest as a well-defined white plaque on the labial or palatal mucosa, called *condyloma latum* (or "split papule," because of its lobulated periphery), or as a mucous patch.

RED LESIONS

Solitary red macules or plaques (*erythroplakia*) are less common in the mouth than white lesions but should be viewed with concern because they may exhibit premalignant dysplasia, carcinoma in situ, or squamous cell carcinoma (see Table 393-3 and Fig. 393-3). One exception is a red macule occurring in the midline of the posterior dorsal tongue, called *median rhomboid glossitis*, which is uniformly benign and usually associated with localized overgrowth of *Candida* species.

ERYTHEMATOUS (ATROPHIC) ORAL CANDIDIASIS

Erythematous (atrophic) oral candidiasis is a chronic condition characterized by erythema and atrophy of the filiform papillae on the dorsal tongue or by

FIGURE 393-5. Hairy leukoplakia. These white plaques on the lateral border of the tongue were the first visible sign of human immunodeficiency virus infection.

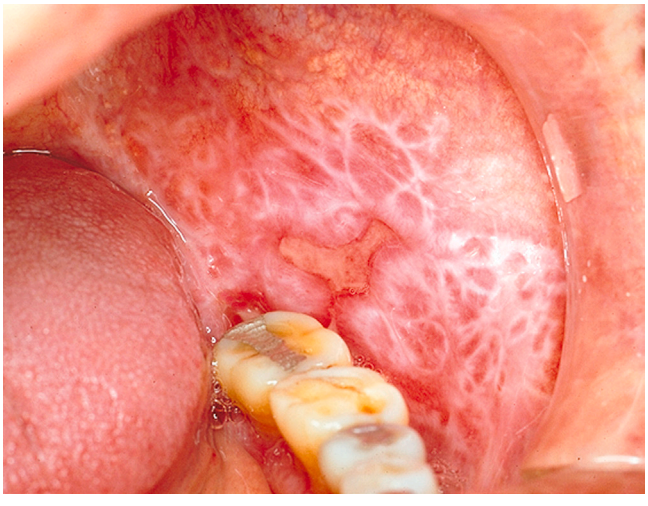

FIGURE 393-4. Lichen planus. A similar-appearing lesion is also present on the right buccal mucosa. Note central pseudomembrane-covered shallow ulceration.

FIGURE 393-6. Geographic tongue. The distribution of these changes on the dorsal tongue may change over time, but they are asymptomatic and diagnosed by their characteristic appearance.

patchy, ill-defined erythema on the palate, tongue, or buccal mucosa (Fig. 393-7). It is usually accompanied by symptoms of oral mucosal burning and sensitivity to spicy foods. It occurs most commonly in patients with chronic salivary hypofunction (e.g., Sjögren syndrome or anticholinergic drug effects), but it also occurs in patients who wear removable dentures infected with *Candida*, in whom mucosal erythema is confined to the denture-bearing area.

For acute or chronic oral candidal infections, systemic or topical antifungal drugs are necessary to resolve the associated lesions. In patients who have clinically apparent salivary production, fluconazole (200 mg on the first day, then 100 mg daily for 2 weeks) is the drug of choice. However, systemic antifungal drugs may not be effective in patients who have severe salivary hypofunction and insufficient saliva to convey the drug from the blood stream to oral mucosa. In such patients, with remaining natural teeth, *oral* antifungal preparations (troches or pastilles), all of which contain cariogenic amounts of sucrose or glucose, *must not be used* to avoid enhancing dental caries. Instead, slow oral dissolution (15 to 20 minutes for 2 weeks) of vaginal nystatin tablets (twice daily) or miconazole tablets (50 mg daily), which contain little or no caries-supporting carbohydrates, is safe and effective; xerostomic patients usually need frequent sips of water to aid in dissolving the tablets. Effective topical or systemic treatment significantly improves oral symptoms. Treatment of denture-associated candidiasis requires that the denture be effectively disinfected and fit well.

The treatment end point is reached when mucosal burning symptoms cease, the patient can again tolerate acidic or spicy foods, and filiform papillae on the dorsal tongue have returned to normal; this recovery takes 2 to 12 weeks, depending on the patient's salivary production and treatment compliance. Recurrence is common in patients with chronic salivary hypofunction or immunosuppression, which necessitates recurring or long-term treatment using a noncariogenic topical antifungal drug that provides a sufficient duration of oral mucosal contact (e.g., nystatin or miconazole tablets).

ANGULAR CHEILITIS

Erythema or crusting of the labial angles is usually caused by *Candida* species (see Fig. 393-7) and is usually associated with intraoral candidiasis. In such cases, topical treatment of the angular cheilitis with clotrimazole (0.75% cream) should be accompanied by intraoral or systemic antifungal treatment, as described previously.

MUCOCUTANEOUS DISEASES

The mucocutaneous diseases of pemphigus vulgaris, mucous membrane pemphigoid, atrophic or erosive lichen planus, and lupus erythematosus can cause similar-appearing oral lesions. Their diagnosis requires examination of a biopsy specimen by routine histopathology and by direct immunofluorescence to identify characteristic deposits of various inflammatory proteins.

The first lesions of pemphigus vulgaris are usually oral mucosal vesicles that rapidly rupture, leaving painful erosions or ulcerations. These are followed by development of skin lesions. Rarely, the lesions remain confined to the mouth (Chapter 406).

Lesions of mucous membrane (cicatricial) pemphigoid are usually confined to the oral mucosa or conjunctivae and occur in patients older than 60 years. They begin as vesicles that quickly rupture, leaving ulcers that are chronic but only moderately symptomatic. Use of topical fluocinonide or clobetasol (0.05% gel or ointment, three times a day, 4 to 12 weeks) for several months, as described for lichen planus, is sometimes sufficient to treat the oral lesions, but most patients also need systemic treatment (Chapter 406). Eye care is also important to prevent ocular damage.

Oral mucosal lesions of lupus may occur in patients who have systemic lupus erythematosus (SLE), in patients who do not have SLE but later develop that disease, or in patients who do not develop SLE (Chapter 245). In this last group, the lesions of mucosal lupus may be analogous to the skin lesions of chronic discoid lupus. They take the form of ulcers with surrounding, radiating hyperkeratotic lines associated with erythema, often resembling lichen planus, but unlike lichen planus are usually solitary or bilaterally asymmetrical. They can be controlled by topical fluocinonide (0.05%, three times a day, 2 to 4 weeks) or intralesional triamcinolone suspension (5 mg/mL), or respond to systemic treatment of SLE.

PIGMENTATIONS

Brown or gray-black macules on the oral mucosa are relatively common and range from benign to highly malignant. They may be caused by localized increase in melanin production, proliferation of melanin-producing cells, or deposition of local or systemically distributed pigmented substances (Table 393-4). Mucosal pigmentation may occur after long-term administration of hydroxychloroquine, minocycline, ketoconazole, methyldopa, or cyclophosphamide. Malignant melanomas can occur at any oral mucosal site, but about 85% develop on the hard palatal mucosa or gingiva, or both. Diagnosis of any of these conditions is established by biopsy and knowledge of relevant underlying conditions.

Lesions of Kaposi sarcoma associated with HIV infection often appear first on the oral mucosa, especially the palate. They begin as macules with a blue or purple color, at which time they must be distinguished from purpura. Later, they spread radially and expand vertically (Chapter 359).

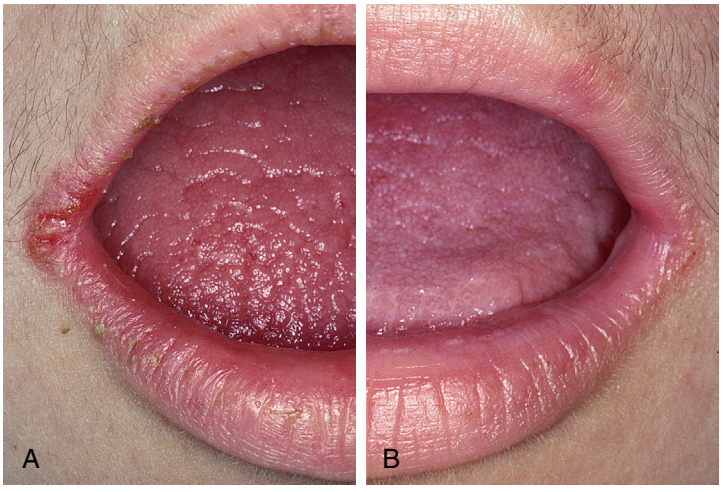

FIGURE 393-7. **Erythematous oral candidiasis. A,** Erythematous candidiasis in a 26-year-old woman with primary Sjögren syndrome, exhibiting symptomatic angular cheilitis, atrophic mucositis, and lingual papillary atrophy. **B,** Asymptomatic and normal-appearing mucosa after treatment with appropriate topical antifungal drugs (see text).

TABLE 393-4 PIGMENTATIONS OF THE ORAL MUCOSA (BROWN OR GRAY-BLACK IN COLOR)

INCREASED MELANIN PRODUCTION (FLAT LESIONS)
Oral melanotic macule
Ephelis (vermilion border)
Systemic diseases: Addison disease, von Recklinghausen disease of skin, Albright syndrome, Peutz-Jeghers syndrome; Laugier-Hunziker syndrome
PROLIFERATION OF MELANIN-PRODUCING CELLS (FLAT OR RAISED LESIONS)
Melanocytic nevi
Melanoma in situ
Malignant melanoma
NONMELANIN PIGMENTATION
Amalgam tattoo
Focal deposition of systemically distributed metal (lead, bismuth, mercury, others) usually at sites of chronic inflammation
Systemically administered drugs (chloroquine, minocycline, ketoconazole, cyclophosphamide)

ORAL SOFT TISSUE TUMORS

A range of oral benign soft tissue tumors should be treated by excisional biopsy.

CONNECTIVE TISSUE HYPERPLASIAS

The most common oral soft tissue tumors are small, pedunculated masses of hyperplastic fibrous connective tissue covered by normal-appearing mucosa (Table 393-5). Solitary lesions are usually found on the inside of the cheeks or lips. Similar lesions may be present at the border of an ill-fitting denture or may occur in clusters on the hard palate under an ill-fitting denture (palatal papillomatosis).

Generalized or multifocal enlargement of the gingiva (gingival hyperplasia) may be caused by chronic administration of phenytoin, cyclosporine, and many of the calcium-channel blocking drugs (e.g., diltiazem, verapamil, or nifedipine; Fig. 393-8). It can also be associated with a hereditary defect or be caused by an infiltration of atypical white blood cells in some types of leukemia (particularly acute monocytic leukemia; Chapter 168) or by uncontrolled diabetes mellitus (Chapter 210).

TABLE 393-5 ORAL SOFT TISSUE TUMORS

CONNECTIVE TISSUE HYPERPLASIA (NORMAL-APPEARING OVERLYING MUCOSA)
Irritation fibroma Denture-associated hyperplasia (fibrous epulis) Palatal papillomatosis (papillary hyperplasia) Generalized gingival hyperplasias Drug-induced (phenytoin, nifedipine, cyclosporine) Hereditary
REACTIVE HYPERPLASIA (ERYTHEMATOUS OVERLYING MUCOSA)
Pyogenic granuloma/pregnancy tumor Peripheral giant cell granuloma Inflammatory gingival hyperplasia Hyperplastic lingual tonsil
EPITHELIAL MASSES (USUALLY IRREGULAR WHITE SURFACE)
Papilloma/oral wart Squamous cell carcinoma Verrucous carcinoma Focal (multifocal) epithelial hyperplasia (Heck disease) Condyloma acuminatum (venereal wart) Keratoacanthoma (on skin aspect of lips)
SALIVARY DUCT OBSTRUCTION (MINOR SALIVARY GLANDS)
Mucocele/ranula (usually fluctuant) Salivary stone (sialolith)
SUBEPITHELIAL NEOPLASMS
Primary connective tissue or salivary gland tumors Metastatic lesions (especially in the mandible) Lymphoma (especially in the palate or posterior mandible) Focal or generalized leukemic infiltrates in the gingiva (especially with acute monocytic leukemia)

FIGURE 393-8. Drug-induced gingival hyperplasia. Similar clinical lesions may occur with prolonged use of various drugs or as a hereditary condition (see text).

REACTIVE HYPERPLASIAS

Small masses with surfaces that are ulcerated or only partially covered by normal-appearing mucosa usually represent reactive lesions in the form of pyogenic granulomas (whose frequency increases during pregnancy), peripheral giant cell granulomas, peripheral ossifying fibroma, or lymphoid hyperplasia of the lingual or other tonsillar tissue. The granulomas are most often located on the gingiva. Rarely, such lesions may represent a metastatic neoplasm.

EPITHELIAL PROLIFERATIONS

Small, white, wartlike epithelial masses are common and can occur in any area of the oral mucosa (Fig. 393-9). They are occasionally classified as epithelial neoplasms, but most do not continue to grow. Human papillomavirus types 2, 6, 11, 13, 32, and 57 have been identified in these wartlike lesions, which are usually classified generically as squamous papillomas. A large wartlike lesion on the oral mucosa or gingiva should raise suspicion of verrucous carcinoma.

SALIVARY MUCOUS RETENTION LESIONS (MUCOCELES)

Mucoceles are small, chronic, or recurring vesicles or bullae that occur commonly on the inside of the cheeks and lips, the posterior soft palate, and the floor of the mouth. They are caused by injury to one of the many submucosal minor salivary glands, resulting in extravasation of mucus, which causes inflammation or blockage of the excretory duct, leading to cyst formation. Mucoceles require conservative surgical excision because simple incision and drainage are usually followed by recurrence.

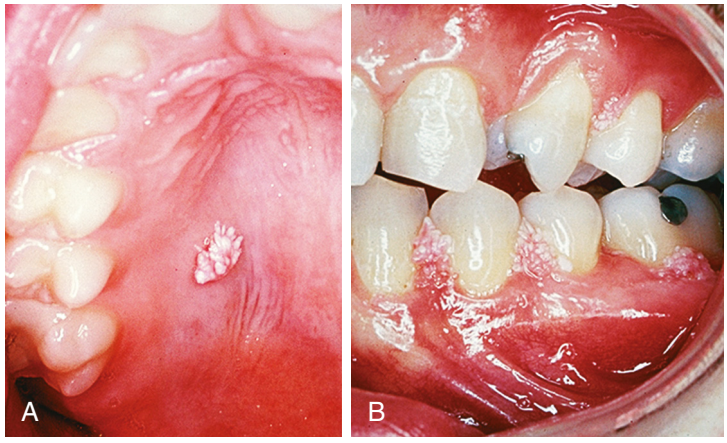

FIGURE 393-9. Papillary epithelial tumors. A, A solitary squamous papilloma. **B,** Multiple gingival papillomas, occurring in all quadrants, from condyloma acuminatum, associated with papillomavirus subtype 6 or 11.

SALIVARY GLAND DISEASES

PRIMARY DISEASES OF SALIVARY GLANDS

Unilateral major salivary gland enlargement that is markedly painful or tender to palpation and has a purulent exudate or nothing expressible from the duct suggests bacterial sialadenitis. Any exudate should be cultured, and initial treatment should be with an oral penicillinase-resistant antibiotic, such as cloxacillin or dicloxacillin 500 mg, every 6 hours.

Painful sialolithiasis usually occurs in submandibular gland ducts, less commonly in the parotid gland, and much less commonly in sublingual and minor salivary glands. Peak incidence is in the third to sixth decades, almost always with pain but occasionally with painless swelling. Diagnosis is clinical, supplemented by ultrasound or computed tomography. Small stones may be expressible or treated by extracorporeal shock wave lithotripsy or endoscopic removal. Larger stones require incisional surgery.

More than 30 types of benign or malignant neoplasms appear as firm and nontender unilateral or bilateral enlargement of a major gland or as a firm submucosal nodule on the palate or the labial or buccal mucosa (Table 393-6). Their causes are unknown, except for Warthin tumor (papillary cystadenoma lymphomatosum) that has a strong association with cigarette smoking. Uncommonly, unilateral major gland enlargement may be reactive—for example, chronic sialadenitis from duct obstruction or inadequately treated bacterial sialadenitis.

Salivary gland tumors (Chapter 176) are relatively uncommon and present as a swelling in one of the major paired salivary glands or in one of the minor glands of the mouth. Most occur in the major glands, with approximately 90% developing in the parotid. The most common benign salivary gland tumor is the pleomorphic adenoma (mixed tumor). Most salivary gland tumors in the parotid gland are benign, in contrast to the sublingual gland, where more than 90% are malignant. Approximately half of tumors in the submandibular and minor glands are malignant. Benign tumors are generally slowly growing, not fixed to the skin, and do not show ulceration of the overlying epithelium. Malignancies generally grow more quickly, are often fixed to the skin or adjacent normal structures, and tend to show ulceration. Adenoid cystic carcinoma has a characteristic local infiltration with prominent perineural spread. Detection of any salivary gland mass lesions should be followed by appropriate imaging, cytology, and biopsy. Both benign and malignant tumors typically are initially treated by surgery.[9]

SECONDARY DISEASES OF SALIVARY GLANDS

BILATERAL SALIVARY GLAND ENLARGEMENT AND DECREASED SALIVARY SECRETION ASSOCIATED WITH SYSTEMIC DISEASES

The best-known cause of bilateral salivary gland enlargement is infection by the mumps virus (Chapter 340) in children. However, the prevalence of mumps decreased in the United States by more than 98% after the introduction of an effective vaccine in 1967, and now there are only a few hundred to a few

TABLE 393-6 CAUSES OF SALIVARY GLAND ENLARGEMENT

USUALLY UNILATERAL
Benign or malignant salivary gland neoplasms (more than 30 different histopathologic types)
Bacterial infection
Chronic sialadenitis (single gland)
USUALLY BILATERAL AND ASSOCIATED WITH SALIVARY HYPOFUNCTION
Viral infection (mumps, cytomegalovirus, influenza, Coxsackie A)
Sjögren syndrome
Chronic granulomatous diseases (sarcoidosis, tuberculosis, leprosy)
Recurrent parotitis of childhood
Human immunodeficiency virus infection/acquired immunodeficiency syndrome
BILATERALLY SYMMETRICAL, SOFT, NONTENDER, PAROTID ONLY
Sialadenosis (asymptomatic parotid enlargement), idiopathic or associated with:
Diabetes mellitus
Hyperlipoproteinemia
Hepatic cirrhosis
Anorexia/bulimia
Chronic pancreatitis
Acromegaly
Gonadal hypofunction
Phenylbutazone use

TABLE 393-7 CAUSES OF DECREASED SALIVARY SECRETION

TEMPORARY
Effects of short-term drug use (e.g., antihistamines)
Virus infections (e.g., mumps)
Dehydration
Psychogenic conditions (e.g., anxiety)
CHRONIC
Effects of chronically administered drugs (particularly antidepressants, monoamine oxidase inhibitors, neuroleptics, parasympatholytics, some combinations of drugs for treating hypertension)
Chronic diseases
Sjögren syndrome
Sarcoidosis
Human immunodeficiency virus or hepatitis C infection
Depression
Diabetes mellitus (uncontrolled)
Amyloidosis (primary or secondary)
Central nervous system diseases
Other effects of treatment
Therapeutic radiation to the head and neck
Graft-versus-host disease
Absent or malformed glands (rare)

thousand cases per year. Uncommonly, a less acute, mumpslike illness may occur in adults in association with cytomegalovirus (Chapter 347), influenza (Chapter 332), or Coxsackie A (Chapter 349) virus infection.

About 15% of patients who meet the criteria for Sjögren syndrome (Chapter 247) may gradually develop chronic bilateral enlargement of major salivary glands that feel firm and nontender or only slightly tender to palpation. Histologically, the tumors begin as a benign lymphoepithelial lesion but after several years of chronicity may transform into an extranodal marginal zone B-cell lymphoma (Chapter 171).

In most patients with Sjögren syndrome, gradually progressive salivary hypofunction can impair speech and swallowing and cause a characteristic pattern of progressive dental caries that leads to excessive tooth loss if not actively prevented. In severe cases, the oral mucosa becomes dry and sticky, saliva is not expressible from the major ducts, and about one third of patients have signs and symptoms of chronic erythematous candidiasis (see earlier discussion and Fig. 393-7).

The salivary component of Sjögren syndrome is diagnosed from a labial salivary gland biopsy specimen that contains three to five minor glands (>10 mm^2 of salivary tissue) and exhibits focal lymphocytic sialadenitis in the absence of nonspecific chronic sialadenitis or another disease, such as noncaseating granuloma. A patient's symptoms of oral dryness (xerostomia) can be caused by a wide variety of conditions (Table 393-7).

Several chronic granulomatous diseases, such as sarcoidosis (Chapter 83), tuberculosis (Chapter 299), and leprosy (Chapter 301), can cause bilateral enlargement and decreased function of salivary glands. The clinical and serologic features of sarcoidosis may occasionally closely mimic those of Sjögren syndrome, and the distinction is best made by minor salivary gland biopsy supplemented with chest radiography.

A few adult patients with HIV infection and most children who are infected in utero develop major salivary gland enlargement and reduced salivary secretion that are caused by lymphocytic infiltration. Parotid gland enlargement usually represents a solid or cystic lymphoepithelial lesion (see Table 393-2).

Recurrent parotitis of childhood includes episodes of unilateral or bilateral parotid enlargement. During flares of this illness, salivary secretion may be reduced, but usually without prominent secondary symptoms or signs. This condition, of unknown cause, usually subsides after puberty.

ASYMPTOMATIC PAROTID ENLARGEMENT (SIALADENOSIS, SIALOSIS)

Parotid glands can develop bilateral, symmetrical enlargement that is soft and nontender to palpation and associated with normal salivary function (see Table 393-6). Diagnosis is established by this clinical presentation and the presence of one of the systemic diseases known to be associated with it: diabetes mellitus (Chapter 210), hyperlipoproteinemia (Chapter 190), hepatic cirrhosis (Chapter 139), anorexia or bulimia (Chapter 200), chronic pancreatitis (Chapter 130), acromegaly (Chapter 205), and gonadal hypofunction. It can also result from use of phenylbutazone or be a reaction to iodine-containing contrast media. Biopsy of the affected glands is not indicated for diagnosis.

IMPAIRED SALIVARY SECRETION WITHOUT GLAND ENLARGEMENT

The common symptom of dry mouth (xerostomia) is most often a side effect of chronically administered drugs. Many classes of drugs reduce unstimulated salivary secretion through anticholinergic or other mechanisms (see Table 393-7). Patients experience these symptoms soon after beginning to use the drug but produce enough saliva during a meal for normal chewing and swallowing. However, the symptoms and associated dental caries are dose dependent and gradually increase with prolonged use of the drug. The classes of drugs producing the most profound effects are most tricyclic antidepressants, most neuroleptics, monoamine oxidase inhibitors, and all anticholinergics. A combination of drugs for treatment of hypertension may also cause symptoms of dry mouth.

Several systemic diseases affect salivary secretion. As noted earlier, most patients with Sjögren syndrome, some with sarcoidosis, and a few patients with HIV infection experience symptoms of dry mouth to various degrees, with or without salivary gland enlargement. In addition, patients who have primary or secondary *amyloidosis* with salivary gland amyloid deposits may develop impaired secretion. The symptom of xerostomia is more prevalent in individuals who exhibit symptoms of depression, even in those not taking drugs for its treatment. Studies done before the availability of antidepressant drugs showed that symptoms of depression were associated with decreased salivary secretion.

Irradiation of the head and neck region to treat a malignancy usually produces profound dry mouth during and after therapy.[10] Secretory capacity recovers only slightly in the months after treatment for patients with solid tumors but recovers significantly for those with multifocal tumors (e.g., Hodgkin disease).

TREATMENT

Significant chronic salivary hypofunction from any cause produces a risk for dental caries (decay) in approximate proportion to the secretory impairment, but caries can largely be prevented if appropriate measures are taken as soon as the hypofunction begins. Remaining teeth should be protected by a comprehensive dental caries prevention program, monitored by a dentist and include daily application of appropriate topical fluorides, removal of dental plaque, counseling on control of cariogenic dietary carbohydrates, and placement of appropriate dental restorations as necessary.

Symptomatic treatment of mild to moderately severe salivary hypofunction can include sialagogs such as sugar-free hard candies or chewing gum, regular sips of water, and use of saliva substitutes at night, but no topical therapy is reliably helpful.[11] If not contraindicated, symptoms of severe hypofunction can be improved by prescribing pilocarpine (5 mg four times a day).[12] Such treatment alone, however, will not prevent dental caries.

Chronic erythematous oral candidiasis is a frequent sequela of chronic salivary hypofunction, and its treatment and retreatment, as noted earlier, substantially improve the patient's oral symptoms.

PERIODONTAL DISEASE

Periodontal diseases are a group of oral infections that affect the periodontium, which are the hard and soft tissues that support and maintain teeth in the jaws. A worldwide problem, it is the most common cause of tooth loss. Periodontal disease in its most prevalent form is associated with excessive build-up of plaque and calculus on teeth and roots. Most cases of periodontal disease begin with inflammation of the gingiva—termed *gingivitis*—that may progress to loss of the supporting bone around the roots of the teeth. Other subtypes of periodontal disease are recognized with differing risk factors and natural histories. The mainstay of treatment is the removal of subgingival calculus and biofilm deposits using mechanical methods (tooth brushing, flossing, scaling, and root planing). Referral for appropriate dental care is indicated. Despite ongoing concerns, there is no current evidence that periodontal disease is an independent risk factor for coronary artery disease.

ACUTE DENTAL INFECTIONS

Localized dental infections respond well to local surgical treatment. Analgesia and nonsteroidal anti-inflammatory drugs are helpful. Antibiotics should be prescribed only in patients with signs of local or systemic spread or in patients who are moderately or severely immunocompromised. Amoxicillin (250 mg three times daily for 3 days) is the first-choice medication, and clindamycin (150 mg four times daily for 3 days) is an alternative in patients who are allergic to it. Spreading dental infections require evacuation of pus without delay, including exploration of all affected fascial spaces and removal of necrotic debris. Parenteral broad-spectrum antibiotics are indicated (e.g., a broad spectrum β-lactam, metronidazole, or gentamicin; see Chapter 258).

394 APPROACH TO THE PATIENT WITH NOSE, SINUS, AND EAR DISORDERS

ANDREW H. MURR AND STEVEN D. PLETCHER

Patients with nose, sinus, and ear disorders may have a variety of chief complaints. Nasal symptoms, including rhinorrhea and congestion, may be due to allergic, infectious, inflammatory, neoplastic, or structural causes. Sinus disorders generally result in concomitant nasal inflammation, so the term rhinosinusitis is preferred. Patients who have rhinosinusitis are more likely to present with purulent rhinorrhea, facial pressure, loss of smell, and pain or headache (Chapter 367). Common ear complaints include pain, tinnitus, loss of hearing (Chapter 396), and vestibular symptoms (Chapter 396). Epistaxis, which is bleeding from the nose, is usually easy to distinguish from hemoptysis from the bronchial tree (Chapter 71) or hematemesis from the gastrointestinal tract (Chapter 121).

NASAL AND SINUS COMPLAINTS

RHINITIS AND RHINOSINUSITIS

DEFINITION

Rhinitis is generally defined as any inflammatory process in the nose, with the common result being a sensation of excess mucous or nasal congestion. Anterior nasal drainage may be perceived by the patient as being accompanied by an activity such as eating (gustatory rhinitis) and may be visible to an observer. Posterior nasal drainage is more nebulous and subjective, but it is very common and is referred to as postnasal drip. Rhinitis and rhinosinusitis can have allergic or nonallergic causes.

Both rhinitis and rhinosinusitis may be categorized as acute, subacute, or chronic, and they can resolve or recur. In general, acute rhinitis and sinusitis describe inflammatory conditions of the nose and sinuses that persist for less than 4 weeks. Chronic rhinitis and sinusitis persist for more than 12 weeks despite treatment. Subacute rhinitis and sinusitis define symptoms that persist between 4 and 12 weeks and resolve completely with treatment. Recurrent acute rhinitis and sinusitis are defined by episodes that occur four or more times per year and persist for 7 to 10 days per episode, but symptoms clear completely between episodes.

EPIDEMIOLOGY

The most common reason for a patient to seek the advice of a physician in the United States concerns problems relating to rhinitis and sinusitis. More than 30 million patient visits per year are devoted to this complaint, and billions of dollars are spent on medications that are expected to improve the condition.

Acute rhinosinusitis accounts for 2 to 10% of U.S. primary care visits. Allergic rhinitis, which is estimated to be the sixth most common chronic illness in the United States, affects between 10 and 20% of adults. Each year, nearly 80 million people in the United States experience 7 days or more of nasal or ocular symptoms as a result of allergic rhinitis, with an estimated annual direct and indirect medical cost of $5 to 8 billion and $11 billion, respectively. The incidence of allergic rhinitis has been increasing, perhaps related to fewer exposures to allergens in early life. The impact of allergic rhinitis also reflects its association with a variety of comorbid conditions, including asthma (Chapter 75), acute and chronic rhinosinusitis, nasal polyposis, secretory otitis media, and sleep disorders (Chapter 374).

PATHOBIOLOGY

Humans normally produce about 2 L of mucus per day from their nasal lining. The nose functions primarily as a humidification and filtration system, with a clean and refreshed nasal mucous blanket serving to trap particulate matter and organisms. The nasal and sinus lining consists of ciliated respiratory epithelium; the cilia function in a highly organized and orderly fashion under normal circumstances to transport particulate matter trapped in the mucous blanket in a consistent fashion so that the mucus can be swallowed, thereby avoiding deposition in the bronchi. The nose also serves as the organ of olfaction (Chapter 395) to allow patients to discern tastes and avoid spoiled foods that could cause illness.

The nose represents the entry site for the majority of respired air, which is warmed, humidified, and filtered in the nose in preparation for the lower respiratory tract. Deposition of allergens, microbes, and other inspired materials presents a challenge to the immune system at this interface with the outside world. The mucosal barrier of the nasal and sinus cavities includes a ciliated respiratory epithelium, where coordinated mucociliary clearance transports particulate matter out of the respiratory tract and into the gastrointestinal tract. The normal microbiome (Chapter 257) of the sinonasal mucosa is thought to contribute to host defense against pathogenic microbes.

Insults to the mucosal barrier, infection, and immune response to inspired particulate matter may result in inflammation of the sinonasal mucosa. The resultant hypersecretion of mucus and tissue edema manifest as the common symptoms of congestion and rhinorrhea. This process may be limited to the nasal cavity (rhinitis) or include both the sinuses and the nasal cavity (rhinosinusitis).

Alterations in the parasympathetic control of vascular tone in the nose may also lead to vascular engorgement and the secretion of mucus. The parasympathetic nervous system controls both vascular tone and mucus production in the nose. Inflammatory conditions, such as the common cold, can cause the nasal and sinus lining to swell, thereby highlighting the nasal cycle governed by parasympathetic neural control. In a normal state, one side of the nose is relatively decongested and one side is relatively congested because of vascular engorgement. This vascular dilation allows humidification and warming of inspired air and can also affect the ability to discern odors in the process of olfaction. During rhinitis, the inflammation exaggerates the normal relative comparison between the decongested and congested sides of the nose and can be perceived as an uncomfortable nasal stuffiness that shifts from side to side over a period of several hours.

Epistaxis, which is bleeding from the nose, is usually easy to distinguish from hemoptysis from the bronchial tree (Chapter 71) or hematemesis from the gastrointestinal tract (Chapter 121).

NASAL AND SINUS COMPLAINTS

RHINITIS AND RHINOSINUSITIS

DEFINITION

Rhinitis is generally defined as any inflammatory process in the nose, with the common result being a sensation of excess mucous or nasal congestion. Anterior nasal drainage may be perceived by the patient as being accompanied by an activity such as eating (gustatory rhinitis) and may be visible to an observer. Posterior nasal drainage is more nebulous and subjective, but it is very common and is referred to as postnasal drip. Rhinitis and rhinosinusitis can have allergic or nonallergic causes.

Both rhinitis and rhinosinusitis may be categorized as acute, subacute, or chronic, and they can resolve or recur. In general, acute rhinitis and sinusitis describe inflammatory conditions of the nose and sinuses that persist for less than 4 weeks. Chronic rhinitis and sinusitis persist for more than 12 weeks despite treatment. Subacute rhinitis and sinusitis define symptoms that persist between 4 and 12 weeks and resolve completely with treatment. Recurrent acute rhinitis and sinusitis are defined by episodes that occur four or more times per year and persist for 7 to 10 days per episode, but symptoms clear completely between episodes.

EPIDEMIOLOGY

The most common reason for a patient to seek the advice of a physician in the United States concerns problems relating to rhinitis and sinusitis. More than 30 million patient visits per year are devoted to this complaint, and billions of dollars are spent on medications that are expected to improve the condition.

Acute rhinosinusitis accounts for 2 to 10% of U.S. primary care visits. Allergic rhinitis, which is estimated to be the sixth most common chronic illness in the United States, affects between 10 and 20% of adults. Each year, nearly 80 million people in the United States experience 7 days or more of nasal or ocular symptoms as a result of allergic rhinitis, with an estimated annual direct and indirect medical cost of $5 to 8 billion and $11 billion, respectively. The incidence of allergic rhinitis has been increasing, perhaps related to fewer exposures to allergens in early life. The impact of allergic rhinitis also reflects its association with a variety of comorbid conditions, including asthma (Chapter 75), acute and chronic rhinosinusitis, nasal polyposis, secretory otitis media, and sleep disorders (Chapter 374).

PATHOBIOLOGY

Humans normally produce about 2 L of mucus per day from their nasal lining. The nose functions primarily as a humidification and filtration system, with a clean and refreshed nasal mucous blanket serving to trap particulate matter and organisms. The nasal and sinus lining consists of ciliated respiratory epithelium; the cilia function in a highly organized and orderly fashion under normal circumstances to transport particulate matter trapped in the mucous blanket in a consistent fashion so that the mucus can be swallowed, thereby avoiding deposition in the bronchi. The nose also serves as the organ of olfaction (Chapter 395) to allow patients to discern tastes and avoid spoiled foods that could cause illness.

The nose represents the entry site for the majority of respired air, which is warmed, humidified, and filtered in the nose in preparation for the lower respiratory tract. Deposition of allergens, microbes, and other inspired materials presents a challenge to the immune system at this interface with the outside world. The mucosal barrier of the nasal and sinus cavities includes a ciliated respiratory epithelium, where coordinated mucociliary clearance transports particulate matter out of the respiratory tract and into the gastrointestinal tract. The normal microbiome (Chapter 257) of the sinonasal mucosa is thought to contribute to host defense against pathogenic microbes.

Insults to the mucosal barrier, infection, and immune response to inspired particulate matter may result in inflammation of the sinonasal mucosa. The resultant hypersecretion of mucus and tissue edema manifest as the common symptoms of congestion and rhinorrhea. This process may be limited to the nasal cavity (rhinitis) or include both the sinuses and the nasal cavity (rhinosinusitis).

Alterations in the parasympathetic control of vascular tone in the nose may also lead to vascular engorgement and the secretion of mucus. The parasympathetic nervous system controls both vascular tone and mucus production in the nose. Inflammatory conditions, such as the common cold, can cause the nasal and sinus lining to swell, thereby highlighting the nasal cycle governed by parasympathetic neural control. In a normal state, one side of the nose is relatively decongested and one side is relatively congested because of vascular engorgement. This vascular dilation allows humidification and warming of inspired air and can also affect the ability to discern odors in the process of olfaction. During rhinitis, the inflammation exaggerates the normal relative comparison between the decongested and congested sides of the nose and can be perceived as an uncomfortable nasal stuffiness that shifts from side to side over a period of several hours.

ABSTRACT

Common sinonasal symptoms, including nasal congestion, nasal obstruction, and nasal drainage, may be secondary to isolated rhinitis (inflammation of the nasal cavity) or inflammation centered in the sinuses with associated nasal involvement (rhinosinusitis). A detailed history and physical examination, including endoscopy, are the mainstays of clinical evaluation. Imaging, specifically computed tomographic scans, are often helpful in evaluating patients who have chronic rhinosinusitis or complications of acute rhinosinusitis. The initial treatments for both disorders include nasal saline irrigations and intranasal corticosteroid sprays. Successful treatment of refractory or severe disease requires a more nuanced understanding of the pathophysiology of nasal and sinus disorders.

Epistaxis, or bleeding from the nose, and ear pain also are common complaints. A systematic approach to the evaluation of these symptoms is described.

Rhinitis

Allergic respiratory diseases result from a hypersensitivity immune reaction to airborne allergens (Table 394-1).[1] Perennial allergic rhinitis may occur year-round. The most common causes include indoor fungi, animal dander, and dust mites. Cat dander is the most common animal allergen, but rodents (mice, rats, guinea pigs, ferrets, hamsters), rabbits, dogs, and birds also may be significant. Dust mites, which live in bedding, pillows, and stuffed animals, are semiseasonal with maximal impact from August to December. Cockroaches and other insects, including gypsy moths, crickets, ladybugs, spiders, and beetles, may be locally important sources of allergen. Seasonal allergic rhinitis is most often triggered by pollens from trees and grasses.

Exposure to allergies results in both early- and late-phase reactions in the nasal cavity. IgE subunits in the surface of mast cells and basophils recognize specific allergens, thereby triggering degranulation of the immune cells with release of histamine and other inflammatory mediators. Within minutes of exposure to the allergen, this process results in tissue edema, nasal congestion, and nasal irritation, frequently associated with sneezing. Approximately 4 to 8 hours after the exposure, chemoattractants and adhesion molecules released in response to the inflammatory mediators promote infiltration of leukocytes, eosinophils, basophils, CD4+ lymphocytes, and monocytes. Activation of these cells results in release of a second wave of inflammatory mediators. Nasal congestion is generally the dominant symptom during the late-phase reaction.

The severity of allergic disease is mediated not only by the current pollen count and exposure to allergens, but also by the cumulative exposure for a given allergy season. Priming is not an allergen-specific phenomenon—patients report increased sensitivity to nonspecific nasal irritants such as perfume and smoke following exposure to allergens. The increased reactivity is thought to be secondary to recruitment of mast cells and basophils as well as neural hyperresponsiveness. Because of this phenomenon, patients may continue to experience symptoms of severe seasonal allergy even after the pollen count of their triggering allergens falls.

Asthma (Chapter 75) and allergic rhinitis share a common pathophysiology and strong epidemiologic association. About 80% of patients with allergic asthma also suffer from allergic rhinitis, and the presence of allergic rhinitis is a risk factor for the development of asthma.

TABLE 394-1 ALLERGENS CAUSING ALLERGIC RHINITIS

COMMON NAME	SEASON IN UNITED STATES
SEASONAL ALLERGENS	
Trees	
Birch	March–May
Cottonwood	April–May
Elm	February–May
Cedar	March–May
Oak	May–June
Maple	March–May
Grasses	
Kentucky blue	Mid-May–June
Timothy	Mid-May–June
Orchard	Mid-May–June
Sweet vernal	Mid-May–June
Fescue	Mid-May–June
Bermuda	Mid-May–June
Weeds	
Ragweed	August–September
Kochia	July–September
Russian thistle	July–September
Sage	July–September
Marsh elder	July–September
English plantain	July–September
Outdoor Molds	
Alternaria	Spring–fall
Cladosporium	Spring–fall
PERENNIAL ALLERGENS	
Household Allergens

Rhinosinusitis

Sinusitis differs from rhinitis in that the term implies an infectious cause rather than physiologic dysfunction. Nevertheless, many different mechanisms of inflammation besides infection may give rise to what is currently generally termed sinusitis.

Acute rhinosinusitis is most frequently caused by a viral infection. Acute bacterial rhinosinusitis may develop secondarily, owing to virus-induced tissue edema and mucus stasis. Odontogenic infection (Chapter 393) may progress to acute or chronic bacterial rhinosinusitis and is a common cause for unilateral infection of the maxillary sinus.

Chronic rhinosinusitis includes both the neutrophilic and eosinophilic drivers of inflammation. Isolated or unilateral disease may occur secondary to chronic suppurative infections, including odontogenic disease and fungal processes, such as a fungus ball or mycetoma.[2] The microbiology of chronic rhinosinusitis differs from that of acute rhinosinusitis, with *Staphylococcus aureus* (Chapter 267), *Pseudomonas aeruginosa* (Chapter 282), and anaerobic bacteria (Chapter 273) commonly cultured. Although the precise role of microbes in the pathophysiology of chronic rhinosinusitis remains unclear, chronically inflamed sinuses are characterized by a loss of bacterial diversity and overgrowth of a pathologic bacterial species.

CLINICAL MANIFESTATIONS

When normal nasal mucosal function is lost, patients often complain of nasal crusting or obstruction, hypersecretion or postnasal drip, coughing, facial pressure, and fatigue. Nasal obstruction that shifts from side to side during the day is common in many types of rhinitis and may be considered an exaggeration of normal physiology.

Rhinitis

Rhinitis is characterized by sneezing, which is often paroxysmal; rhinorrhea with clear, watery secretions; nasal congestion; and itching in the nares and palate. In allergic rhinitis, these symptoms are generally associated with allergic conjunctivitis manifested by ocular itching, lacrimation, and conjunctival injection. Severe conjunctivitis is less common in perennial allergic rhinitis than in seasonal allergic rhinitis. Lethargy, fatigue, arthralgias, myalgias, and cognitive impairment frequently accompany allergic rhinitis. Fever is not a feature of allergic rhinitis, even though the lay term for this condition is hay fever, which reflects the influenza-like nature of this disease. The natural history of allergic rhinitis is for symptoms to worsen inexorably during several weeks in the presence of ongoing allergen exposure. Symptoms often do not peak until well after the peak in pollen counts, and then they persist after pollen counts have declined.

Rhinosinusitis

Cardinal symptoms of acute rhinosinusitis (Table 394-2) include purulent nasal drainage; nasal obstruction; and facial pain, pressure, or fullness. Additional signs and symptoms include fever, cough, fatigue, reduced or absent sense of smell, dental pain, and ear symptoms such as pressure and fullness. The sign with the highest diagnostic value is purulent nasal discharge or posterior pharyngeal discharge. The presence of purulent nasal drainage generally supports the diagnosis of acute bacterial sinusitis, but culture of the drainage does not necessarily correlate well with actual pathogenic bacteria found on direct sinus culture.

TABLE 394-2 CARDINAL SYMPTOMS OF ACUTE SINUSITIS

CARDINAL SYMPTOMS	OTHER SIGNS/SYMPTOMS
Facial pain, pressure, or fullness	Hyposmia/anosmia
Nasal obstruction	Fatigue
Nasal purulent discharge	Dental pain
	Fever
	Cough
	Ear pressure or fullness

In chronic rhinosinusitis, typical symptoms include nasal obstruction or congestion, drainage, diminished sense of smell, and facial pressure. Acute pain and fever are uncommon with chronic disease. Patients with chronic sinusitis often note a dull facial pressure that seems to worsen with dependency. Other factors favoring a diagnosis of bacterial sinusitis over viral sinusitis include length of illness beyond 10 days or when a patient's symptoms worsen within 10 days after an initial improvement in symptoms.

DIAGNOSIS

History

A thorough history should probe whether patients have tried over-the-counter or prescription medications, including antihistamines, decongestants, mucolytics, analgesics, mast cell stabilizers, and even steroids, and whether they have helped improve the condition. In addition, other prescription medications have side effects that affect nasal physiology, including antihypertensive medications that cause systemic vasodilation, aspirin, corticosteroids, and antibiotics. Specific questions regarding allergies are important, including seasonality or environmental triggers, the presence or absence of pets, food sensitivities, recent changes in environment, and living conditions, with a focus on old or new carpets, mattresses, furnace filters, or freshly painted interior walls. A patient should be questioned about past allergy skin testing or other testing.

A recent history of other family members or coworkers being ill with an upper respiratory viral infection suggests an infectious over an environmental process. A careful past medical history should allow one to determine whether relevant conditions such as previous nasal surgery or trauma, granulomatous diseases, cystic fibrosis (Chapter 77), rheumatologic conditions, immune deficiencies (Chapter 231), or other problems may be contributing factors. Unilateral nasal congestion raises concern for either an anatomic abnormality, such as septal deviation, perhaps related to previous trauma, a polyp or other neoplastic mass, or perhaps even a foreign body.

Physical Examination

The nose should be inspected with a nasal speculum to assess nasal septal anatomy (Fig. 394-1), the most caudal aspect of the inferior turbinates (Fig. 394-2), and the possibility of large nasal polyps (Fig. 394-3 and 394-4) or other masses. In patients with allergic rhinitis, the physical examination may reveal pale and swollen inferior turbinates, whereas copious nasal secretions are more apparent with viral infections. By spraying the nose with a topical decongestant such as phenylephrine (Neo-Synephrine) or oxymetazoline, the middle meatus, which is the air space between the middle turbinate and lateral nasal wall, can often be visualized to assess for nasal polyps or purulent discharge. Examination of the mouth and oropharynx, including the posterior pharyngeal wall, with a tongue blade if necessary, can sometimes identify a stream of postnasal discharge or pus. Sinus palpation and transillumination, although part of the art of medicine, are not sufficiently reliable for diagnosis. The patient's ability to open the mouth without limitation helps exclude trismus, which can sometimes be caused by a dental infection or a deep neck infection.

A complete examination of the head and neck should be performed to look for signs of recent or old trauma such as ecchymosis under the eyelids, swelling of the soft tissue of the face, or deviation of the nasal dorsum. The neck should be palpated for adenopathy (Chapter 154) or other masses.

A basic eye examination should be performed to assess pupillary function, extraocular movements, and possible nystagmus (Chapter 392). An ear examination should be conducted to assess the tympanic membranes bilaterally. In patients with an abnormality of the tympanic membrane or concomitant complaints of hearing loss or disequilibrium (Chapter 396), pneumatoscopy using an air bulb attached to the otoscope can be used to insufflate the ear canal and assess for mobility of the tympanic membrane; decreased mobility suggests a middle ear effusion. Weber and Rinne testing using a 512-Hz tuning fork screens for conductive hearing loss, especially unilateral loss.

Endoscopic examination of the nose, almost always performed by a specialist, is the "gold standard" for evaluating rhinitis and sinusitis. A flexible or rigid fiberoptic scope can allow fine inspection of the septum, turbinates, middle meatus, and sphenoethmoid recess, as well as direct inspection of the

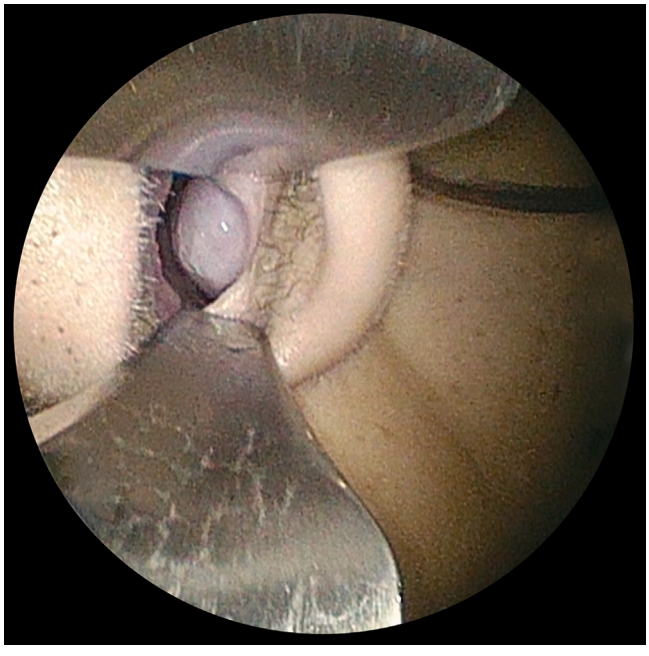

FIGURE 394-2. Examination of the left nasal cavity using a nasal speculum demonstrates an edematous, pale inferior turbinate consistent with allergic rhinitis.

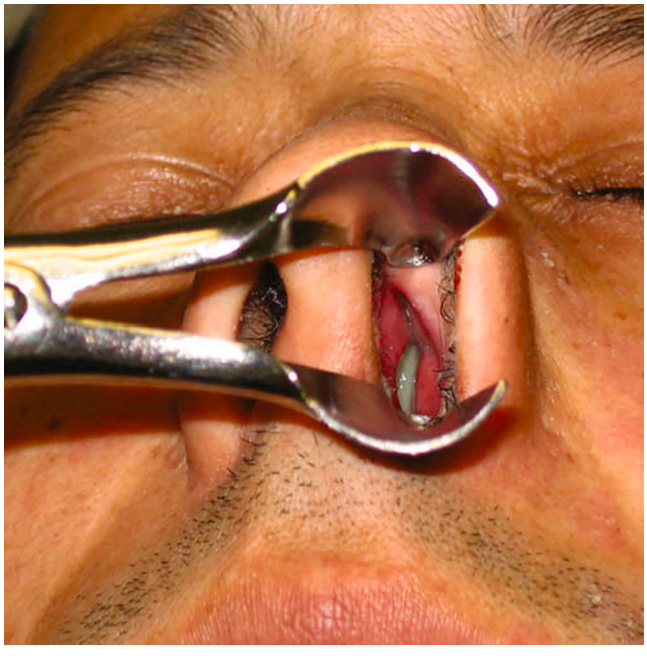

FIGURE 394-1. Purulent drainage from the middle meatus seen on anterior rhinoscopy.

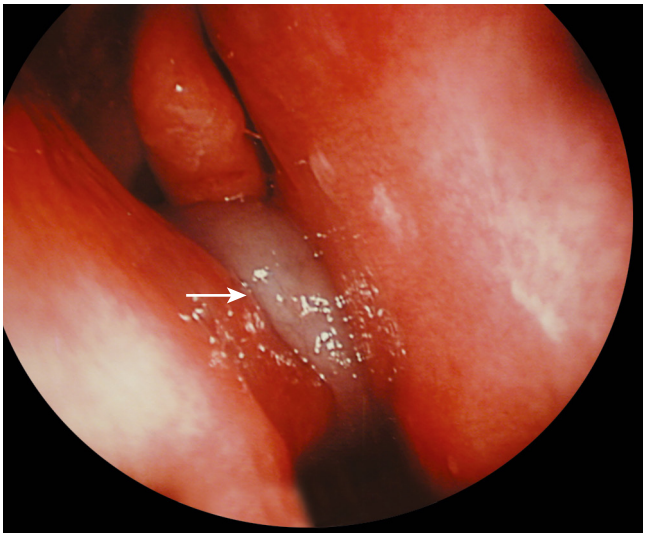

FIGURE 394-3. Nasal polyp in the right nasal cavity. A polyp is seen on the right side just inferior to the middle turbinate, next to the nasal septum. It is paler than the surrounding tissue.

nasopharynx, orifice of the eustachian tube, and fossa of Rosenmüller, which is just rostral to the Eustachian tube in the nasopharynx and is often the site of origin of nasopharyngeal carcinoma (Chapter 176). Flexible endoscopy can be used to further inspect the oropharynx, larynx, and most of the hypopharynx (Chapter 397). Mucus samples can be obtained for culture.

Laboratory Findings

Cultures

Cultures of the nostril or lower nasal cavity are not typically useful and are not recommended. An endoscopically guided culture of the middle meatus by a specialist may help guide treatment for acutely ill immunocompromised patients, for patients suspected of having acute bacterial rhinosinusitis, for patients with refractory chronic rhinosinusitis, or for those whose sinusitis is suspected of causing secondary meningitis, epidural or subdural abscess, brain abscess, orbital involvement, or cavernous sinus thrombosis.

FIGURE 394-4. Nasal polyp clearly visible on physical examination.

Other Tests

A nasal smear can reveal eosinophils, which is consistent with allergic rhinitis. Likewise, skin testing or radioallergosorbent testing can help pinpoint allergic triggers (Chapter 230). In patients with acute sinusitis, a white blood cell count with differential may be useful. In patients with chronic sinusitis, serum immunoglobulin levels can be helpful: highly elevated IgE levels can raise suspicion for allergic fungal sinusitis, whereas low levels of IgG and other subclasses suggest immunodeficiency (Chapter 231). If the patient has chronic nasal crusting as a primary complaint, screening serologic tests for sarcoid (Chapter 83), granulomatosis with polyangiitis (Chapter 249), T-cell lymphomas (Chapter 171), syphilis (Chapter 295), tuberculosis (Chapter 299), Sjögren syndrome (Chapter 247), and other chronic inflammatory diseases can be considered. Relatively rare infections such as rhinoscleroma also may be present, so biopsy and cultures may be indicated to help reveal a diagnosis. Use of illicit substances should be considered because cocaine and other illicit drugs may cause chronic nasal crusting. Toxicology screening can be useful if substance abuse (Chapter 365) is suspected. In a patient with a lifelong history of sinusitis since childhood, cystic fibrosis should also be considered (Chapter 77).

Imaging

Imaging is not indicated for routine rhinitis, acute rhinosinusitis without suggestion of complications, or chronic rhinosinusitis when objective evidence of inflammation is confirmed on nasal endoscopy (Fig. 394-5). Computed tomography (CT) is frequently used to provide objective evidence of inflammation in patients whose symptoms are suggestive of chronic rhinosinusitis (Fig. 394-6), in patients who have nasal polyps (Fig. 394-7), to identify the extent of disease, to exclude impending complications. A CT scan also is required to define anatomy before endoscopic sinus surgery. The additional of intravenous contrast is helpful in patients with suspected complications of sinusitis, including orbital or intracranial spread of infection.

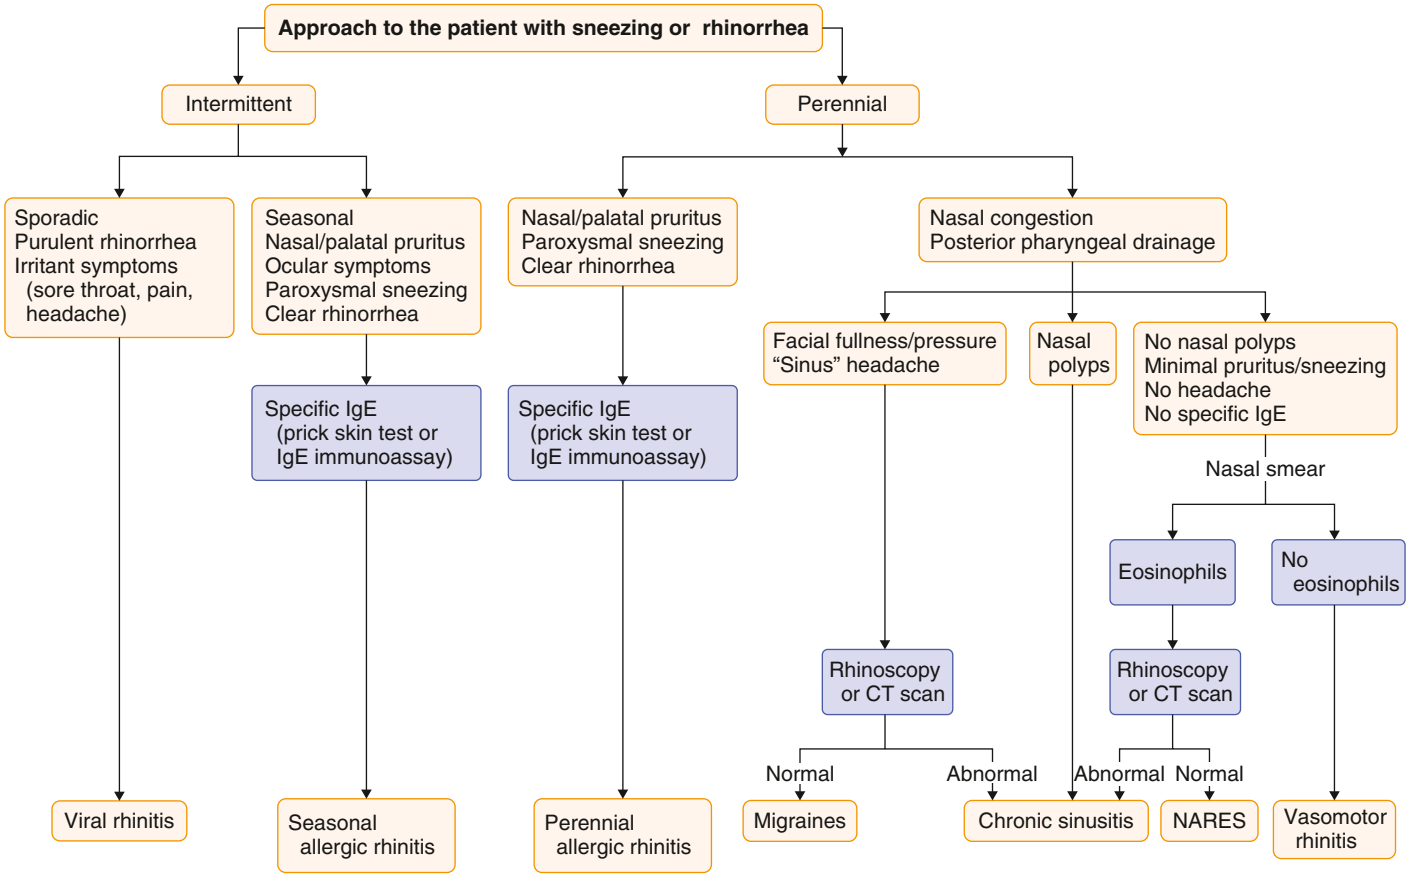

FIGURE 394-5. Approach to the patient with rhinitis symptoms. CT = computed tomography; HA = headache; IgE = immunoglobulin E; NARES = nonallergic rhinitis with eosinophilia syndrome.

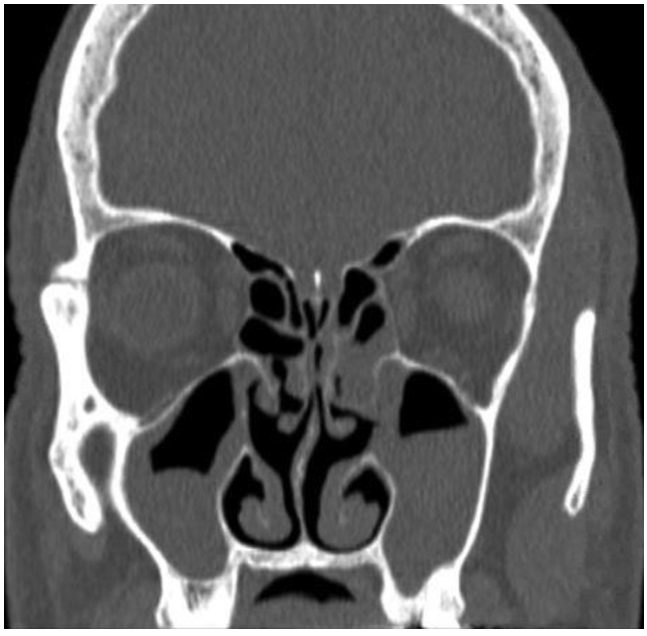

FIGURE 394-6. Coronal noncontrast computed tomographic image of a patient with chronic sinusitis. There is partial opacification of the maxillary sinuses bilaterally. Also noted is partial opacification of a left ethmoid cell.

Plain films have little utility and are not generally recommended given the superiority of CT imaging. Magnetic resonance imaging (MRI) is occasionally helpful, especially when there is a concern for a sinonasal tumor, invasive fungal sinusitis, or an encephalocele.

Differential Diagnosis, Rhinitis

Rhinitis is primarily a clinical diagnosis with multiple specific causes (see Fig. 394-5 and Table 394-3) based on symptoms and exposure history. The diagnosis of allergic rhinitis[3] may be confirmed by the demonstration of specific IgE antibodies reactive to the relevant allergen through either positive allergy skin test responses or IgE immunoassays (Video 394-1). Prick skin testing is safe, specific, and rapid, and it is the diagnostic test of choice for identifying relevant allergens. IgE immunoassays are an appropriate alternative when skin testing is not available. However, a negative IgE immunoassay with a strong clinical suspicion suggests the need for a specialty referral.

Viral rhinitis[4] may be difficult to distinguish from seasonal allergic rhinitis. In contrast to the pervasive eosinophilia in allergic rhinitis, viral rhinitis often produces thicker, purulent secretions, with neutrophils present on the nasal smear. Conjunctival symptoms are less pronounced, and on physical examination, the nasal mucosa is erythematous and swollen.

Abuse of topical nasal decongestants (e.g., oxymetazoline), with chronic reflex vasodilation, has historically been the most common cause of rhinitis medicamentosa; however, cocaine and nasal narcotic abuse is another frequent cause of this condition. Chronic unilateral nasal blockage suggests an anatomic defect, often a deviated septum, but such blockage can also result from polyps, foreign bodies, and tumors. This history necessitates referral for rhinoscopy (Video 394-2).

An abnormal neurogenic response to irritants (e.g., cold air, pollutants, cigarette smoke, strong odors, alcohol, foods) is the predominant feature of vasomotor rhinitis. Patients with vasomotor rhinitis typically have chronic nasal congestion and posterior pharyngeal drainage, but they lack the paroxysmal sneezing, rhinorrhea, pruritus, conjunctivitis, and systemic complaints typical of patients with allergic rhinitis. In addition, eosinophils are absent in their nasal mucus.

Laryngopharyngeal reflux is another possible cause of nasal congestion and posterior pharyngeal drainage that often occurs in association with cough and hoarseness. These patients are often otherwise asymptomatic from "silent" gastroesophageal reflux (Chapter 124), thereby making recognition challenging. Because symptoms may not resolve until after several months of aggressive reflux treatment and because proton pump inhibitors by themselves may not prevent reflux of digestive enzymes (e.g., pepsin) or other stomach-derived irritants, proper diagnosis can be daunting.

Atrophic rhinitis is characterized by atrophy of the nasal epithelium and is associated with complaints of nasal congestion and a perceived bad odor. It is observed in elderly patients, but the most common cause is devascularization secondary to nasal surgery or trauma.

A disease termed nonallergic rhinitis with eosinophilia syndrome[5] presents with symptoms similar to those of vasomotor rhinitis. The syndrome is diagnosed by performing a nasal smear for eosinophils; however, a CT scan or rhinoscopy is required to exclude chronic sinusitis or nasal polyposis because the symptoms of these conditions may overlap. In contrast to vasomotor rhinitis, nonallergic rhinitis with eosinophilia syndrome is more responsive to intranasal cromolyn and intranasal corticosteroids.

Cerebrospinal fluid (CSF) rhinorrhea may be misdiagnosed as chronic rhinitis. CSF leaks are typically unilateral and may occur spontaneously[6] or secondarily following sinonasal surgery or trauma. Patients with spontaneous CSF leaks often have underlying intracranial hypertension (Chapter 367) and comorbid obesity (Chapter 201). Patients with CSF leaks are generally able to demonstrate their unilateral rhinorrhea as a flow or individual clear droplets from the affected nasal cavity when leaning over or bearing down with a Valsalva maneuver. This fluid may be collected and sent for beta-2 transferrin testing to confirm the CSF origin.

Rhinitis and atrophic rhinitis may be the presenting symptom of a systemic disorder. Granulomatosis with polyangiitis (Chapter 249), sarcoidosis (Chapter 83), and T-cell lymphomas (Chapter 171) may affect the nasal cavity, most commonly resulting in nasal congestion, epistaxis, and pain. Granulomatosis with polyangiitis and T-cell lymphomas are frequently destructive within the nasal cavity, where they lead to erosion of the septum (septal perforation) and inferior turbinates. Intranasal drug use (Chapter 365) can also cause local tissue destruction.

Differential Diagnosis, Rhinosinusitis

Rhinosinusitis must be differentiated from rhinitis. Rhinosinusitis may be caused by viral infection, bacterial infection, fungal infection, and allergy (Table 394-4).

Rhinosinusitis

Acute rhinosinusitis requires the presence of either nasal obstruction/congestion or nasal drainage (anterior or posterior) combined with either facial pain/pressure or loss of smell. From a clinical perspective it is important to distinguish between allergic versus infectious causes and, if infectious, between acute viral rhinosinusitis (common cold; Chapter 329) from acute bacterial rhinosinusitis. An acute onset of inhalant allergy is often seasonal or can be traced to a particular precipitant. A rapid onset of sinus-related symptoms suggests a viral upper respiratory infection, especially if the patient also has typical systemic symptoms, such as arthralgia, myalgia, fever, chills, gastrointestinal symptoms, and cough in addition to nasal congestion, postnasal drip, and headache. Viral disease can progress to a secondary bacterial infection; patients with symptoms that persist without evidence of improvement for at least 10 days or have acute worsening of symptoms following an initial improvement are diagnosed clinically as having acute bacterial rhinosinusitis.[7] Rare complications of acute rhinosinusitis include spread of infection to the orbit, intracranial space, soft-tissues are associated with fulminant bacterial infection. Acute bacterial rhinosinusitis causes facial pressure and purulent postnasal discharge.

Chronic rhinosinusitis encompasses multiple pathophysiologic mechanisms and implies a prolonged course of sinus symptoms that have been refractory to symptomatic treatment over a period of at least 12 weeks.[8] Chronic sinusitis presents with nasal congestion, nasal drainage, facial pressure, and sometimes anosmia (see Table 394-2). In contrast to acute (infectious) sinusitis, headaches are an unusual manifestation of either perennial rhinitis (allergic or nonallergic) or chronic sinusitis, and virtually all patients who complain of "sinus headaches" suffer from atypical migraine headaches (Chapter 367) that occur in a bilateral distribution involving the maxillary or ophthalmic branches of the trigeminal nerve. This distribution, especially when it is combined with vasomotor symptoms such as nasal congestion, rhinorrhea, and conjunctival injection, often leads to misdiagnosis as chronic sinusitis or rhinitis. Because of this overlap in symptoms among chronic sinusitis, perennial rhinitis, and atypical migraine headaches, as well as their synergistic influences on each other, objective evaluation with either CT or rhinoscopy is usually required to establish the diagnosis of chronic sinusitis (Table 394-5).

Endoscopically guided culture techniques combined with CT are the best way to diagnose or exclude infectious rhinosinusitis. CT can reveal mucoceles, which are blocked individual sinuses that continue to secrete mucus and can slowly erode bone, expand to involve the eye and brain, or become acutely infected. Mucus retention cysts, often present in the maxillary sinus, are

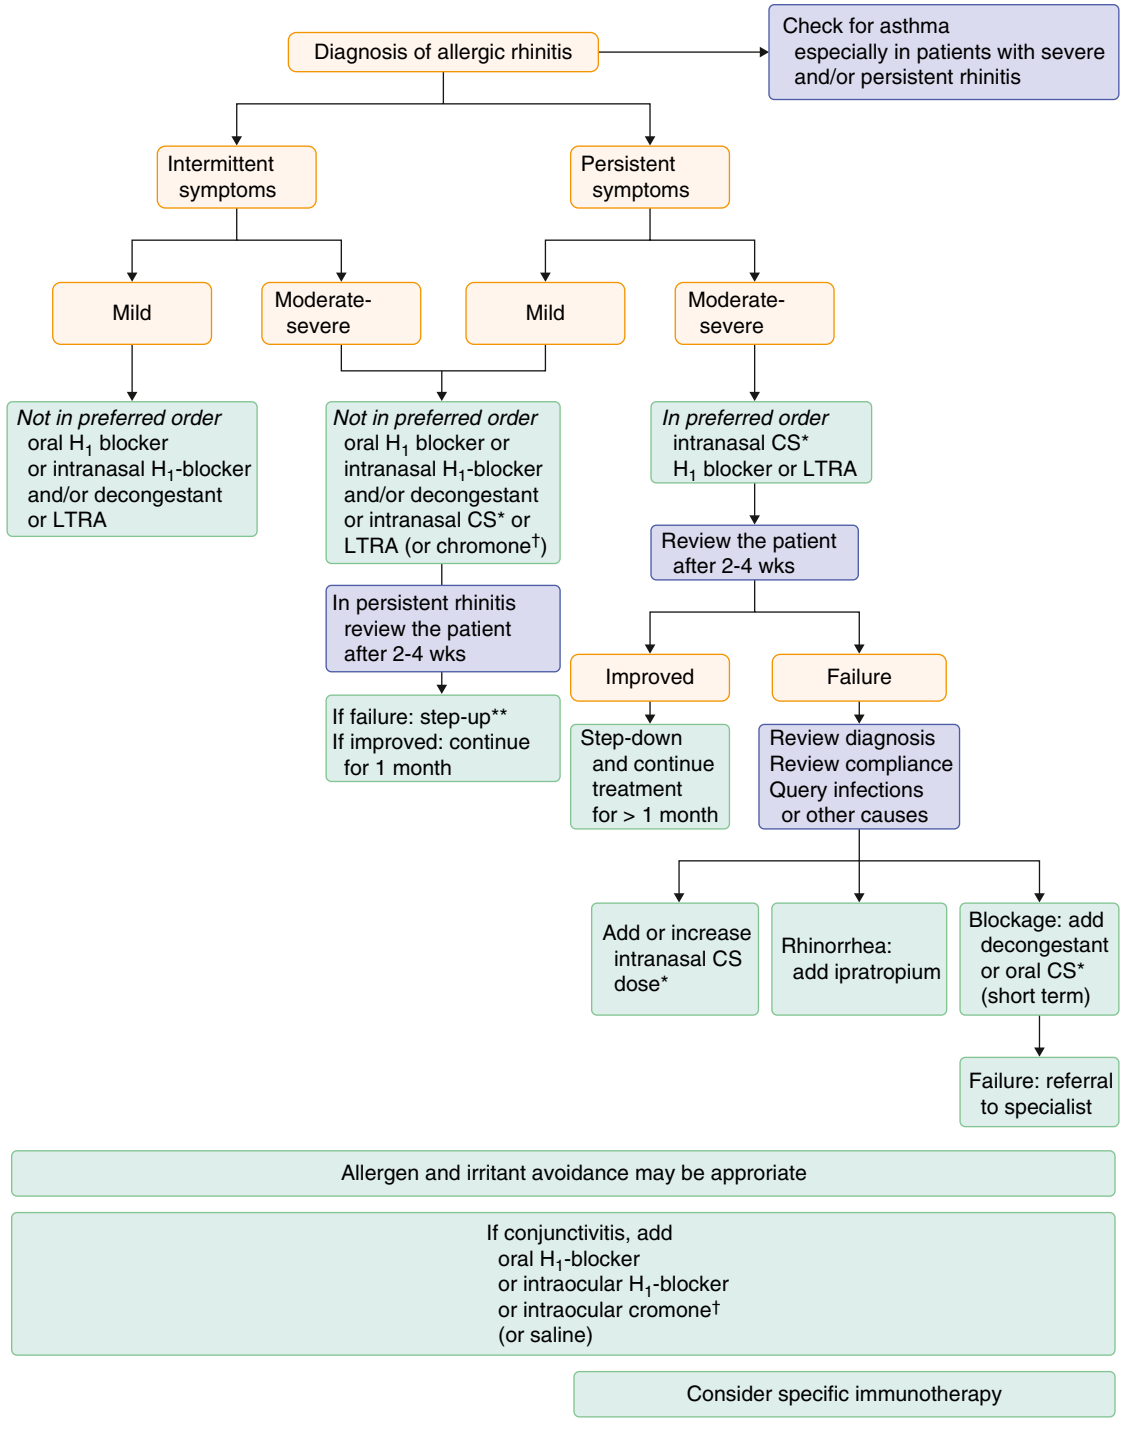

FIGURE 394-7. Algorithm for the management of allergic rhinitis. See text for specific drugs and doses. CS = corticosteroids; LTRA = leukotriene-receptor antagonist. *Total dose of topical and oral corticosteroids should be considered if inhaled corticosteroids are used for concomitant asthma. **Step-up with an LTRA or cromolyn (see text). †Chromone is available as cromolyn. (From Bousquet J, Schünemann HJ, Samolinski B, et al. Allergic rhinitis and its impact on asthma [ARIA]: achievements in 10 years and future needs. *J Allergy Clin Immunol*. 2012;130:1049-1062.)

manifested as a spherical opacification; an estimated 10% of the population has a mucus retention cyst, which is usually asymptomatic.

Immunosuppressed patients are at risk for invasive fungal sinusitis,[9] a life-threatening acute infection of the sinuses. The fulminant version of invasive fungal disease typically occurs with severe neutrophilic dysfunction in patients who have a hematologic malignancy or poorly controlled diabetes. Chronic invasive fungal disease may be seen with long-term use of systemic corticosteroids, after solid organ transplantation, or with chronic immunodeficiency syndromes

A mycetoma, which is an isolated "fungus ball" in a sinus, has a characteristic hyperdensity within a sinus opacification. Mycetomas (Chapter 314) are noninvasive but may erode bone because of pressure necrosis over a long period of time.

TREATMENT

Medical Therapy

Allergic Rhinitis

The three categories of treatment for allergic rhinitis are avoidance of allergens, pharmacotherapy, and immunotherapy.[10] The severity and duration of symptoms, as well as patient's preference, help determine the appropriate treatment options. Antihistamines (oral or intranasal) are the primary treatments for seasonal, mild disease, whereas intranasal corticosteroids are preferred for perennial, severe disease (see Fig. 394-7). If an antihistamine is to be added to an intranasal corticosteroid, an intranasal antihistamine is preferred.[A1] Second-generation antihistamines have a long duration of action and are nonsedating. These once-daily agents include cetirizine (10 mg), levocetirizine (5 mg), fexofenadine (180 mg), desloratadine (5 mg), and loratadine (10 mg). The intranasal

TABLE 394-4 HETEROGENEITY OF CHRONIC SINUSITIS

PHENOTYPE	CHARACTERISTIC
Infectious	Very unusual as a cause of chronic sinusitis
Inflammatory	Develops secondary to anatomic obstruction of the sinus ostia; often resolves after surgical correction Bacterial biofilms contribute to presence and severity Infrequently associated with nasal polyps
Hyperplastic eosinophilic	Prominent eosinophilic infiltrate with systemic eosinophilia Frequent association with allergies and asthma Usually associated with nasal polyps
Allergic fungal	Often unilateral; presents as expansive, dense infiltrate on CT scan Associated with elevated total IgE and specific IgE to colonizing fungi
Aspirin-exacerbated respiratory disease	Intense eosinophilic infiltrate Usually associated with nasal polyps and asthma Exacerbations of upper and lower respiratory disease (asthma) after ingestion of aspirin and nonselective COX1 inhibitors

COX1 = cyclooxygenase 1; CT = computed tomography; IgE = immunoglobulin E.

antihistamines azelastine and olopatadine, have a more rapid onset of action than oral antihistamines and also are effective for nonallergic forms of rhinitis. The benefit of antihistamines diminishes in patients with continuous allergen exposures, such as perennial allergic rhinitis caused by indoor allergens or after several days of continuous exposure to seasonal allergens; in such settings, these drugs often prove to be little better than placebo.

Oral decongestants such as pseudoephedrine (30 to 60 mg every 4 to 6 hours; not more than 240 mg per 24 hours) treat nasal stuffiness but are mild stimulants and may produce rebound congestion and headaches. These drugs are usually used in combination with antihistamines to control the full spectrum of allergic rhinitis symptoms. Antihistamines and decongestants alone generally do not provide satisfactory relief in patients with moderate to severe allergic rhinitis.

Intranasal corticosteroids, including triamcinolone acetonide (two sprays [55 μg] to each side of the nose every day), mometasone furoate (two sprays [50 μg] to each naris every day), fluticasone propionate (two sprays [50 μg] to each naris every day), and budesonide (two sprays [32 μg] to each naris every day) (Table 394-6), are the treatments of choice for patients with moderate to severe seasonal allergic rhinitis or perennial allergic rhinitis.[A2] Intranasal corticosteroids provide a 50 to 90% reduction in symptoms compared with 20 to 30% for oral antihistamines.

TABLE 394-5 DIAGNOSTIC CRITERIA FOR CHRONIC SINUSITIS

Symptoms for more than 3 months:
Mucopurulent nasal drainage
Nasal obstruction
Reduced sense of smell
Facial pressure, or fullness
Supported by an objective finding:
Nasal or middle meatus polyps
Edema or purulence in middle meatus
Paranasal *sinusitis* on endoscopy or CT scan

CT = computed tomography.

Clinical practice guideline (update): adult sinusitis. *Otolaryngol Head Neck Surg*. 2015;152:S1-S39.

Leukotriene antagonists (zileuton [1200 mg twice daily], zafirlukast [20 mg twice daily], montelukast [10 mg once daily])[A3] have a confirmed efficacy in allergic rhinitis that is comparable to that of antihistamines but do significantly improve sneezing, rhinorrhea, nasal congestion, ocular symptoms, and quality of life in patients with seasonal allergic rhinitis and perennial allergic rhinitis. For otherwise refractory symptoms, a 6-day course of oral corticosteroids (e.g., methylprednisolone, 8 mg four times daily for 1 day, 4 mg four times daily for 2 days, 4 mg three times daily for 1 day, 4 mg twice daily for 1 day, 4 mg once daily for 1 day) can be tried. Nasal cromolyn stabilizes mast cells and mediates additional anti-inflammatory activities. Although it is not as effective as intranasal corticosteroids, cromolyn provides relief in patients with mild to moderate symptoms. The value of cromolyn is mitigated by the need for frequent doses (four times/day), a lack of efficacy in approximately 30 to 40% of recipients, and the superior efficacy of intranasal corticosteroids in controlled studies. Cromolyn may be especially useful preventively (e.g., immediately before cat exposure). Ocular cromolyn has been especially useful in the treatment of allergic conjunctivitis. No significant side effects are associated with its use.

Infectious Rhinitis

Viral rhinitis is treated with supportive care, including fluid replacement and treatment of the febrile component of the syndrome with acetaminophen or nonsteroidal anti-inflammatory medications. Steam has a mild decongestant effect, and vitamin C and good nutrition may help hasten the resolution of symptoms. Oral decongestants (e.g., pseudoephedrine, 120 mg every 12 hours for several days), mucolytics (e.g., guaifenesin, 200 to 400 mg every 4 to 6 hours for several days), and ipratropium bromide (0.03 or 0.06%, two sprays on each side of the nose every 12 hours for several days) are of potential benefit.

Acute Rhinosinusitis

Acute rhinosinusitis, including acute bacterial rhinosinusitis, may be managed with supportive care, including saline irrigations, nasal steroid sprays, antipyretics, decongestants, and analgesics. The best clinical predictors of the presence of acute bacterial rhinosinusitis rather than viral rhinosinusitis include persistent symptoms for 7 or more days without evidence of clinical improvement; high fever (>39° C [102° F]) with purulent nasal discharge or facial pain for at least 3 to 4 consecutive days; or the onset of worsening symptoms more than 5 days after the onset of an apparent viral upper respiratory tract infection. Even for patients who meet the clinical criteria for acute bacterial rhinosinusitis,[11] however, the impact of antibiotic treatment is modest; about 85% of patients will have complete resolution of symptoms at 10 to 14 days; watchful waiting is a reasonable alternative.[A4] Engaging patients in a discussion of the modest impacts of antibiotics and potential risks of treatment is recommended to determine a patient-specific treatment plan.

Patients with a suspected complication of acute bacterial sinusitis (e.g., infection involving the orbit, intracranial cavity, or other adjacent soft tissues) should be treated immediately with antibiotics and referred to an otolaryngologist for urgent evaluation. Patients who have refractory disease, who are immunocompromised, or who require intensive care may benefit from procedures to decompress the maxillary sinus and sample its contents for culture to guide antibiotic therapy.

The preferred antibiotic regimen is amoxicillin (500 mg three times daily), or amoxicillin-clavulanate (875 mg/125 mg orally twice daily),[A5] with no evidence that higher doses are more beneficial, except perhaps for increasing to 2000 mg/125 mg orally twice daily in patients who have fever greater than 39° C (102° F), are immunocompromised, or have recently received antibiotics. In patients who are allergic to penicillin, alternatives include doxycycline (100 mg orally twice daily), trimethoprim-sulfamethoxazole (160/800 mg orally twice daily), or a fluoroquinolone (e.g., levofloxacin 500 mg orally daily or moxifloxacin 400 mg orally daily). By

Ciclesonide	50 µg	6 yr	Once daily
Ciclesonide HFA	37 µg	12 yr	Once daily

*Intranasal corticosteroids are generally administered at 2 sprays per nostril.

comparison, macrolides and second- and third-generation oral cephalosporins are not recommended because of high levels of resistance. The usual course of therapy is 7 days, regardless of the medication chosen. Patients who initially choose watchful waiting should be treated with antibiotics if their symptoms do not resolve within 1 week. Intranasal saline irrigations, using either physiologic or hypertonic saline, may be a useful adjunct in patients with acute bacterial rhinosinusitis, but neither topical decongestants nor antihistamines are useful.

If patients worsen despite 72 hours of antibiotic treatment or do not improve after 5 to 7 days of treatment, further evaluation should include a CT scan to localize the infection and detect complications, as well as cultures—either by direct sinus aspiration or endoscopically guided cultures of the middle meatus. Other cultures are unreliable.

Chronic Rhinosinusitis

The mainstays for treating the symptoms of chronic rhinosinusitis are saline irrigation[A6] and intranasal corticosteroids,[A7] (e.g., triamcinolone acetonide, two 55-µg sprays to each side of the nose every day; mometasone furoate, two 50-µg sprays to each naris every day; fluticasone propionate, two 50-µg sprays to each naris every day; or budesonide, two 32-µg sprays to each naris every day) for 6 weeks.[12] Unfortunately, relief may be limited, and patients frequently require oral corticosteroids (e.g., prednisone 40 mg per day for 5 days, 30 mg per day for 5 days, 20 mg per day for 5 days, and 10 mg per day for 5 days) to achieve appreciable improvement. Oral antibiotics are of little value,[13] except in patients who are experiencing an acute exacerbation. Endoscopically obtained cultures of the middle meatus can help define which patients may improve with culture-guided antibiotic treatment. Antifungal agents, including itraconazole in an oral or aerosolized form and amphotericin B in an aerosolized form, do not appear beneficial in the treatment of typical chronic sinusitis.

Biologic treatments initially designed to treat asthma (Chapter 75) hold promise for the treatment of chronic rhinosinusitis with type 2 inflammation, but the precise integration of biologic treatments into the care of patients with chronic rhinosinusitis and nasal polyps remains in evolution.[14] Because of their cost and the need for indefinite treatment, most recommendations suggest limiting their use to patients who have recurrent disease following endoscopic sinus surgery or who have comorbid conditions that preclude surgery.[15] Dupilumab[A8] (300 mg subcutaneous injection every 2 weeks), omalizumab (subcutaneous injection, dosing dependent upon weight and total IgE count), and mepolizumab (100 mg subcutaneous injection every 4 weeks) are approved for the treatment of chronic rhinosinusitis associated with nasal polyps.

Surgical Therapy

Patients who have severe symptoms, who fail to respond to therapy, or who have unusual, or resistant, or recurrent infections should be sent to a specialist for further evaluation and treatment (Table 394-7). Surgery is recommended in patients with benign neoplasms, mucoceles, juvenile nasopharyngeal angiofibroma, and some types of malignancies. Surgery can correct septal deviations and anatomically related nasal obstruction.[A9]

Surgery on the inferior turbinates may be beneficial for refractory allergic rhinitis.[A10] For patients who have chronic rhinosinusitis and who do not receive adequate benefit from medical treatment, endoscopic sinus surgery may be considered. Surgery allows removal of inflammatory tissue and mucus along with enhanced access for future topical treatments and clinic interventions. Patients should be monitored following surgery to tailor their medical regimen and maintain the benefits of surgery. Even with aggressive medical therapy and appropriate surgical intervention, patients with severe type 2 inflammation may experience early recurrence of inflammatory sinonasal disease with nasal polyps. Functional endoscopic surgery, which is designed to preserve mucociliary function and is performed with endoscopes through the nostril without skin incisions, can be useful for recurrent acute sinusitis and chronic rhinosinusitis.

TABLE 394-7 WHEN TO REFER A PATIENT WITH PRESUMED BACTERIAL RHINOSINUSITIS TO AN EAR, NOSE, AND THROAT SPECIALIST

Temperature >39° C (>102° F); orbital edema; severe headache, visual disturbance, altered mental status, meningeal signs
Failure to respond to more than two courses of antimicrobial therapy
Nosocomial infection, anatomic abnormalities
Immunocompromise or multiple comorbidities
Unusual or resistant pathogens
Fungal sinusitis or granulomatous disease
Recurrent episodes suggesting chronic sinusitis

PREVENTION

Avoidance and Environmental Control

When feasible, avoidance or elimination of the source of the allergen is the treatment of choice for patients with allergic rhinitis. Dust mite avoidance involves removing reservoirs for mite growth (i.e., use allergen-impermeable mattress and pillow covers), keeping the relative humidity lower than 50%, washing bedding in hot water (130° F) to kill mites, and wearing a simple mask when dust is being disturbed. Many of the measures suggested for mites are also helpful for fungi, especially dehumidification. Windows, shower curtains, and indoor plants are important sites for fungal growth and can be treated with mild fungicides (dilute household bleach).

In some houses, and particularly urban apartment blocks, large numbers of cockroaches are present, and IgE sensitivity is common. Although it may be difficult to kill cockroaches in an apartment, it is usually possible to keep a house clear of cockroaches by using chemical sprays and traps. Air-conditioning with closed windows is useful for reducing seasonal allergens, and the dehumidification provided by air-conditioning also mitigates the mite and indoor mold load.

Pets, especially cats and dogs, are the most preventable source of allergic diseases. The dominant rodent allergen is a urinary protein, and rodents, like cats, can deposit large quantities of allergen in a house.

Immunotherapy

Immunotherapy may be used for prevention in patients who have refractory disease or in patients with moderate to severe symptoms who want to de-escalate pharmacotherapy. This immunomodulatory approach is the only known option to affect the natural history of disease and may limit the future development of asthma. Subcutaneous immunotherapy regimens generally involve weekly antigen injections with a gradual escalation of the antigen dose. Efficacy depends on delivery of the correct antigen, regular injections for 3 to 5 years, and administration of an adequate dose of the allergen (10 to 15 µg, a dose much higher than that used historically). Immunotherapy is associated with a small risk of fatal anaphylaxis (about 3 fatalities/year in the United States, of 2 million people receiving this form of treatment) and must be administered in a facility where resuscitation equipment and trained personnel are available. The effects of subcutaneous immunotherapy persist for many years after a 3- to 5-year course of treatment has been discontinued, and they could be lifelong.

Sublingual immunotherapy provides significant clinical benefit along with reduced need for pharmacologic therapy for numerous allergens including grass,[A11] ragweed, and dust mites.[A12,A13] Sublingual immunotherapy treatments are FDA approved for timothy grass or cross-reactive grass pollens, for a panel of different grass pollens, for dust mites, and for ragweed pollen.[16] For example, administration of a house dust mite sublingual allergen immunotherapy tablet (6 or 12 development units) is an experimental option for reducing asthma exacerbations in patients who are allergic to house dust mites. As with subcutaneous immunotherapy, long-term clinical benefits are observed after it is discontinued, although recurrences are common after 5 to 10 years and some sublingual preventive treatments may lose efficacy within 3 years.[A14]

Severe responses to immunotherapy are exceedingly rare, but the potential for anaphylaxis and even death requires vigilance. Practitioners who perform skin testing and administer allergy shots require appropriate training and access to emergency protocols and medications. In comparison to subcutaneous

administration, sublingual immunotherapy is sufficiently safe to permit home administration.

NASAL POLYPS

During the evaluation of symptoms of rhinitis or sinusitis, the physical examination may reveal nasal polyps. Nasal polyps typically begin near the ethmoid sinuses in the middle meatus and extend into the nose, where they block the nasal airway and/or the sinuses. Most chronic rhinosinusitis with polyps is associated with type 2 inflammation, which is an inflammatory pathway that involves interleukin (IL)-4, IL-5, IL-13, and IgE and that is strongly associated with tissue eosinophilia, comorbid asthma, and severe sinus disease.[17] However, some patients with chronic rhinosinusitis and polyps demonstrate a predominately neutrophilic inflammatory response mediated by IL-17. A subset of patients with nasal polyps will be found to have aspirin sensitivity[18] and asthma related to arachidonic acid metabolism and upregulation of leukotriene production. Human papillomavirus (Chapter 344) may cause an inverted papilloma, which presents as a polyp causing unilateral nasal obstruction. This initially benign neoplasm responds to surgical excision but can transform to frank malignancy. Polyps are also seen in patients with cystic fibrosis, especially patients with the delta F508 mutation (Chapter 77). They are also seen in allergic fungal sinusitis, which is manifested by an elevated IgE level, positive fungal cultures (usually for aspergillosis), Charcot-Leyden crystals on histopathology, characteristic densities on CT, and nasal polyposis that is often, but not always, unilateral. Antral choanal polyps may extend into the nasal cavity or nasopharynx and cause obstruction.

CLINICAL MANIFESTATIONS

Nasal polyps often present with symptoms of nasal blockage and anosmia along with typical symptoms of rhinitis. When polyps are present, the nasal congestion is often unrelenting. Sometimes, patients with prolonged symptoms will present with a visible mass in their nostril. Rarely, facial asymmetry or orbital involvement will be the presenting sign of long-ignored nasal polyps. Patients with nasal polys may be more likely to complain of facial or ear pain than patients with rhinitis without polyps.

DIAGNOSIS

Nasal polyps will be visible in a careful examination (see Fig. 394-3 and 394-4), and their extent can be shown on a CT scan (Fig. 394-8). Unilateral nasal polyposis is suggestive of an antral choanal polyp, malignancy, inverted papilloma, or allergic fungal sinusitis; early biopsy is recommended.

TREATMENT

Benign inflammatory nasal polyps frequently respond to oral steroids, either in a tapered burst dose or, in rare cases, in small amounts of titrated daily oral steroids such as prednisone (40 mg per day for 5 days, followed by 30 mg per day for 5 days, followed by 20 mg per day for 5 days, followed by 10 mg per day for 5 days) or methylprednisolone (beginning with 24 mg the first day and tapering by 4 mg each subsequent day for 6 days).[19] The combination of systemic steroids with doxycycline (e.g., 100 mg twice daily) may be even more effective, and the leukotriene antagonist montelukast (10 mg once daily) can be helpful as well.[A15] Topical steroids are also efficacious for treating nasal polyps.[A16] In adults with symptomatic chronic sinusitis and nasal polyps that are refractory to intranasal corticosteroids, the addition of subcutaneous dupilumab (300 mg every 2 weeks),[A17] omalizumab (dosing depending upon weight and total IgE count) under expert guidance,[A18] or mepolizumab (100 mg subcutaneously every 4 weeks)[A19] to a corticosteroid nasal spray can reduce polyp burden and symptoms as well as the need for systemic corticosteroids in patients with chronic sinusitis and nasal polyps.[20] For patients with aspirin allergy, desensitization to aspirin or biologics may be helpful.[21]

Surgery for benign nasal polyposis can improve symptomatic control and reduce the need for oral steroids.[A20] Surgery is always recommended for inverted papillomas, antral choanal polyps, and most mucoceles, and surgery is likely to be helpful if acute sinusitis has caused central nervous system complications such as meningitis (Chapter 381), epidural abscess, subdural abscess, brain abscess (Chapter 382), or orbital abscess. Occasionally, surgery will be required when an untreated and aggressively growing polyp causes orbital or skull base erosion. Allergic fungal sinusitis is often treated with a combination of surgery, corticosteroids, and sometimes immunotherapy.

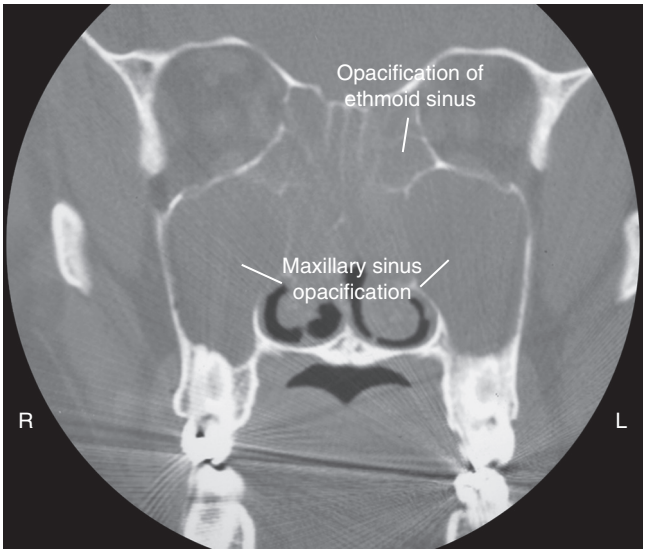

FIGURE 394-8. Computed tomography showing bilateral nasal polyposis of a chronic nature.

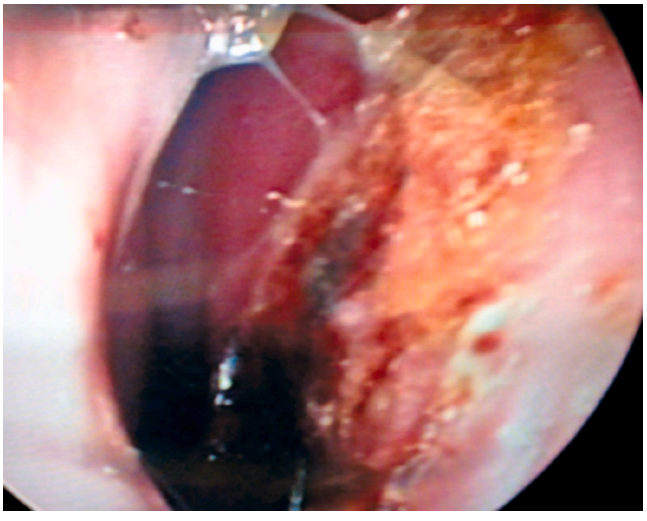

FIGURE 394-9. Dilated nasal vessels and crusting typical of a patient with epistaxis.

EPISTAXIS

Epistaxis (a bloody nose) can be an isolated or recurrent problem. Patients with nosebleeds frequently have systemic conditions that contribute to the severity of their bleeds. Persistent bleeding may result from hypertension,[22] oral anticoagulants, antiplatelet agents, or any underlying platelet disorder (Chapters 158 and 159) or clotting deficiency (Chapter 160).

DIAGNOSIS

For a patient with epistaxis, it is first critical to determine the severity of the blood loss. Physical examination should focus on inspection of the anterior septum, which is the most frequent point of origin for epistaxis. Frequently, dilated blood vessels on the caudal septum can be seen with anterior rhinoscopy (Fig. 394-9). Rarely, recurrent bleeding may be a sign of a sinonasal neoplasm. Bleeding in combination with unilateral nasal obstruction, epiphora, facial numbness, pain, ipsilateral serous otitis media, and/or cervical adenopathy are all concerning findings that warrant referral to a specialist. Lesion such as nasopharyngeal carcinoma (Chapter 176), juvenile nasopharyngeal angiofibroma, found in young men, may present with recurrent epistaxis and associated findings. A family history of nosebleeds in patients with recurrent epistaxis and multiple small visible vascular lesions on the fingers, lips, or tongue should raise concern for hereditary hemorrhagic telangiectasia (Fig. 394-10; Chapter 159).[23]

FIGURE 394-10. **Telangiectasias on the lower lip in a patient with recurrent nosebleeds and a diagnosis of hereditary hemorrhagic telangiectasias (HHT).**

TREATMENT AND PREVENTION

Epistaxis can be treated by local pressure, packing (using nasal sponges, balloons, or by ½-inch by 72-inch gauze impregnated with petroleum jelly), humidification, and hydration.[24–26] Hospitalization and transfusion are rarely required. Offending anticoagulation medications should be reduced in dose or discontinued temporarily if possible. Topical vasoconstrictive medication such as oxymetazoline spray, two sprays on each side of the nose every 12 hours for 3 days, can help limit persistent epistaxis.[27] Hemostatic agents such as Gelfoam-thrombin combination products also can be useful in treating refractory epistaxis or epistaxis in the presence of coagulopathy. Topical bevacizumab, estriol, and tranexamic acid are not routinely recommended, but topical tranexamic acid can reduce the need for nasal packing.[A21]

Patients with refractory bleeding may be treated with surgical arterial clipping or interventional neuroradiologic arterial occlusion. If a focal vascular lesion or exposed vessel is identified, it may be cauterized with silver nitrate, bipolar cautery, or laser treatment.

Dry airflow often precipitates nosebleeds in susceptible patients; maintaining a moist nasal environment through the use of topical ointments, gels, or viscous sprays helps limit bleeding. Humidifiers also may be used to reduce dryness.

EAR PAIN

DEFINITION

Ear pain (otalgia; Table 394-8) is discomfort perceived by a patient in the area of the lateral temporal bone. Although the discomfort often can be localized by the patient, at times the cause of the discomfort may in fact be distant from the site where the pain is felt. This referred pain can be due to problems in the oral cavity, oropharynx, hypopharynx, or larynx.

PATHOBIOLOGY

The ear is well supplied with sensory nerves and is positioned on the side of the skull. The ear is divided into the outer ear, or pinna, and the ear canal; the middle ear, which encompasses the tympanic membrane and ossicles; and the inner ear, which consists of the cochlea and the vestibular canals, including the utricle and saccule. In general, otalgia is due to problems in the outer or middle ear. The trigeminal nerve innervates the anterior-superior quadrant of the pinna, whereas the C2 and C3 cervical cutaneous nerves innervate the rest of the majority of the outer ear. However, there are contributions by the 9th and 10th nerves in the ear canal and even a small patch of sensory innervation by the 7th nerve in the posterior superior ear canal. It is the overlap in distribution of the 9th and 10th cranial nerves that establishes the anatomic basis for referred otalgia in diseases of the oral cavity, oropharynx, and larynx. Additionally, otalgia may be caused by disorders of the temporal mandibular joint, which is located just anterior to the external auditory canal. Therefore, ear pain may be due to inflammatory conditions of the skin of the outer ear, the ear canal, or the middle ear, or it may be due to disease processes unrelated to the ear itself.

CLINICAL MANIFESTATIONS

Patients with ear pain often have complaints referable directly to the ear itself. In cases of otitis externa, obvious erythema and swelling of the skin of the ear canal may be present. Limited physical manipulation of the ear may be excruciating for the patient with acute otitis externa. In chondritis of the pinna, which may be related to rheumatologic disorders, infection, or trauma, the entire pinna may be swollen and painful (Fig. 394-11). Hearing loss accompanying otalgia may indicate middle ear disease, especially otitis media. Patients sometimes complain of pain in the ear after air travel or driving from a mountainous region. Quick changes in pressure, such as encountered in scuba diving, may indicate barotrauma (Chapter 82), in which the Eustachian tube is unable to compensate rapidly enough for the changes in pressure that are encountered. Pain also may be a post-traumatic symptom from relatively minor percussion injury, more severe head trauma, or percussion injury related to a blast. Pain related to noise exposure may also indicate damage to the middle ear or even the inner ear. Deep-seated boring pain over the temporal area accompanied by retro-orbital pain can be due to petrous apex disease, including petrous apicitis.

TABLE 394-8 CAUSES OF OTALGIA

CAUSES OF OTALGIA	EXTERNAL EAR	MIDDLE EAR	UPPER AERODIGESTIVE TRACT
Likely	Otitis externa Herpes zoster oticus Chondritis Foreign body	Acute otitis media Acute eardrum perforation Barotrauma Chronic otitis media with impending complication	Tonsillitis Tonsillar abscess Deep neck abscess Tumor (especially base of the tongue, tonsil, hypopharynx, larynx, nasopharynx)
Unlikely	Malignant otitis externa Tumor	Tumor	

DIAGNOSIS

History

A patient with ear pain should be asked to reveal the location of the discomfort, the duration of the symptoms, and any activities related to onset of the condition. As an example, recent swimming would make otitis externa ("swimmer's ear") more likely, whereas a recent upper respiratory infection with hearing loss would suggest otitis media. Questions should address possible hearing loss, vertigo, otorrhea, hoarseness, voice change, dysphagia, odynophagia, dyspnea, hemoptysis, hematemesis, and weight loss. A social history with specific concentration on tobacco and alcohol use should be obtained. A possible family history of upper aerodigestive tract and nasopharyngeal carcinoma should be sought. A surgical history can reveal distant ear or throat surgery.

Physical Examination

A complete head and neck examination, including general assessment for trauma and a basic eye examination, is required. The outer ear and pinna should be examined first. The ear canal should first be palpated and then inspected. An otoscope with a pneumatic bulb attachment is critical to establish the presence or absence of a middle ear effusion. Inspection of the tympanic membrane should be accomplished with notations made about translucency of the eardrum, position and definition of the malleus (Fig. 394-12), presence or absence of a perforation (Fig. 394-13), and the eardrum's mobility with the ear canal sealed and a puff of air delivered by the pneumatic bulb (pneumotoscopy). A middle ear effusion (Fig. 394-14) may be seen in patients with resolving infection or chronic dysfunction of the eustachian tube. Blood may be seen especially after barotrauma but also with the secretory otitis media (Fig. 394-15). Examination with a 512-Hz tuning fork should be performed to differentiate conductive (diseases of the auditory canal and middle ear) from sensorineural (diseases of the inner ear) hearing loss by the lateralization of midline bone conduction (Weber test) and whether air conduction is superior to bone conduction (Rinne test) (see Chapter 396).

Facial nerve function should be assessed (Chapter 366) by determining whether the patient can raise the eyebrows, close the eyes, wrinkle the nose, and purse the lips. The presence or absence of nystagmus should be recorded. Inspection of the nose, oral cavity, oropharynx, and neck should be accompanied by cranial nerve examination (Chapter 366). Palpation of the tongue and tonsils is especially important if the ear pain is intense and persistent. A careful neck examination should be performed to look for masses. Oral cavity infections (Chapter 393), such as a peritonsillar abscess or severe tonsillitis,

FIGURE 394-11. Swollen ear pinna in a patient with chondritis.

FIGURE 394-12. This view of a normal tympanic membrane shows a right ear with a translucent drum, a prominent umbo of the malleus and just posteriorly the incudostapedial joint is visible. There is no evidence of effusion, but pneumotoscopy would be necessary to ascertain that finding. (Image courtesy of Dr. Jeffrey Sharon.)

may arise as ear pain, and the physical examination should reveal trismus, erythema, mass effect, and other common signs of pharyngitis.

Laboratory

An audiogram can assess hearing loss (Chapter 396). A tympanogram measures compliance of the middle ear system and is an accurate method for diagnosis of a middle ear effusion, often as a result of otitis media. Cultures are rarely performed because they require tympanocentesis, and cultures of the external ear can reveal a vast variety of organisms that are often treated empirically with antibiotics. If a fever and middle ear effusion are present and neck stiffness is found on physical examination, lumbar puncture may rarely be recommended because of the small chance that otitis media can cause central nervous system complications such as meningitis.

Imaging

In general, imaging is indicated if complications of acute or chronic otitis media are suspected or to look for occult causes of otalgia in the upper

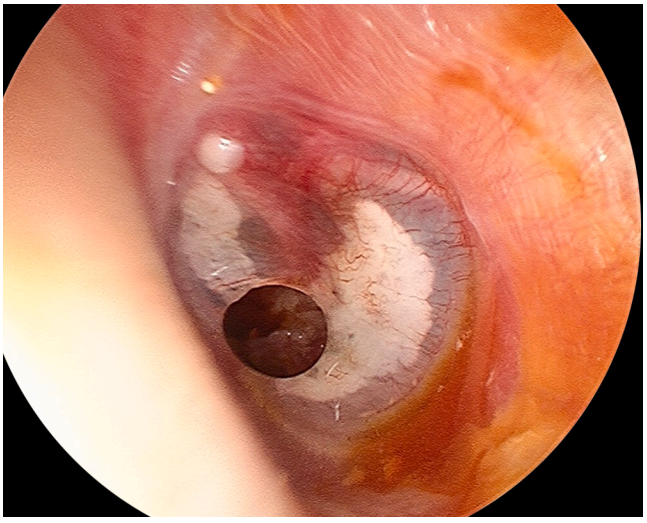

FIGURE 394-13. This left tympanic membrane has a small perforation surrounded by white plaque-like dystrophic calcification, which is referred to as tympanosclerosis.

FIGURE 394-14. A fluid meniscus of straw-colored effusion can be seen filling the middle ear space behind the left tympanic membrane. (Image courtesy of Dr. Jeffrey Sharon.)

aerodigestive tract. If a patient is suspected of having meningitis, epidural or subdural abscess, brain abscess, or sagittal sinus thrombosis, contrast imaging is mandatory. Imaging is also useful for operative planning in patients with chronic otitis media or (rarely) to evaluate for the presence of tumors in the middle or external ear.

Differential Diagnosis

Otitis externa, which is an infection of the skin of the ear canal, is often due to manipulating the ear after swimming or trying to scratch an ear canal that itches because of skin irritation. Patients exhibit erythema and edema of the canal skin often accompanied by a purulent exudate (Fig. 394-16). Patients with otitis externa and may experience extreme pain on manipulation of the ear canal. In the presence of concomitant cranial neuropathies, especially in diabetic or otherwise immunocompromised patients, malignant otitis externa with osteomyelitis should be suspected. Inspection of the tympanic membrane may reveal fluid consistent with otitis media; the tuning fork examination should support the presence of conductive hearing loss. Vesicles on the conchal portion of the pinna, especially when accompanied by facial nerve paralysis, strongly suggest herpes zoster oticus with Ramsay Hunt syndrome (Chapter 346). Perforation of the eardrum suggests either acute or chronic otitis media, traumatic perforation, or possibly cholesteatoma (Chapter 396) if the perforation is in the posterior-superior quadrant. Chronic draining otorrhea

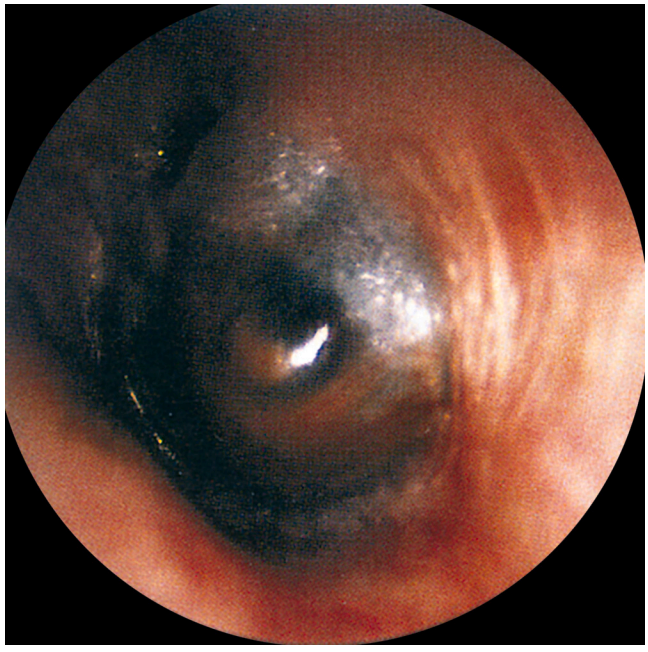

FIGURE 394-15. Blood in the middle ear (hemotympanum). Causes include otitic barotrauma, secretory otitis media, and a high jugular bulb. (From Dhillon RS, East CA, eds. *Ear, Nose and Throat and Head and Neck Surgery*, 2nd ed. Edinburgh: Churchill Livingstone; 1994:26.)

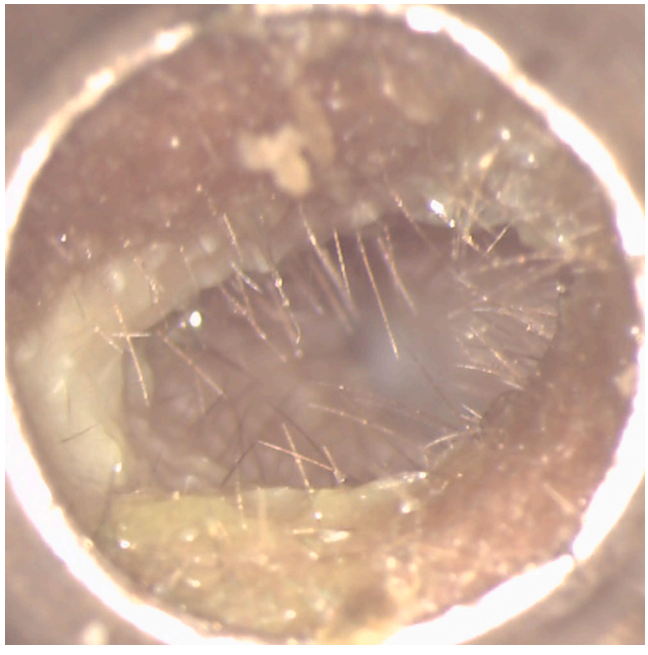

FIGURE 394-16. This view through a speculum shows an erythematous external auditory canal with exudate consistent with otitis externa. The fine hairs of the lateral external auditory canal are visible. The bright ring is a reflection from the speculum as seen through a microscope. Treatment is with topical antibiotic drops with or without topical corticosteroids.

of long standing with a deep boring pain and perforation of the tympanic membrane suggests a complication of otitis media.

If findings on ear and cranial nerve examination are negative but the patient's complaints of otalgia are persistent, special effort needs to be made to visualize the upper aerodigestive tract, including the nasopharynx, oral cavity, oropharynx, larynx, and hypopharynx, to be sure that infection or tumor is not present in these hard-to-examine areas. Flexible fiberoptic nasopharyngoscopy is a standard examination in these circumstances, and imaging such as MRI with contrast also can be very useful.

TREATMENT

Otitis externa is often treated with meticulous office debridement using a microscope and the application of antibiotic drops (ciprofloxacin, tobramycin, neomycin, polymyxin B), with or without hydrocortisone in various combinations.[28,29] In patients who are suspected of having a perforation of the tympanic membrane, aminoglycosides, which can be toxic to the inner ear, should be avoided. In patients who have substantial edema of the ear canal with narrowing of its lumen, a small wick or sponge is placed in the ear canal to help maintain patency of the canal and allow facile application of the medications.[30]

For acute otitis media, oral antibiotic treatment is directed at eradicating *Haemophilus influenzae* (Chapter 277), *Moraxella catarrhalis* (Chapter 277), *Streptococcus pneumoniae* (Chapter 268), and *Staphylococcus aureus* (Chapter 267) with amoxicillin, with or without clavulanate (e.g., amoxicillin 500 mg three times daily for 7 days or amoxicillin clavulanate [875 mg/125 mg] twice daily for 7 days), as for sinusitis. In general, antibiotics provide somewhat better short-term outcomes but at the expense of significantly more diarrhea and rashes. In patients with middle ear effusions, antimicrobial treatment may effectively reduce the duration of effusion, but whether it improves hearing is unknown.[A22] In some patients, the natural history of acute otitis media is acute perforation of the eardrum, which often results in otorrhea, relief of pain, and spontaneous healing of the perforation. Most middle ear effusions clear spontaneously within 3 months regardless of whether they are treated. A persistent effusion in an adult should prompt evaluation of the nasopharynx to exclude the presence of a mass impacting the eustachian tube. Chronic suppurative otitis media responds to oral antibiotics and probably to topical antibiotics.[A23,A24]

Traumatic perforations of an eardrum usually heal without surgical intervention, but if an eardrum perforation persists for more than about 3 months, surgical closure and the use of tympanoplasty with or without mastoidectomy can be contemplated, although tympanostomy tubes do not prevent recurrent otitis media in children.[A25] Chronic draining perforations, especially if located in the posterior-superior quadrant of the tympanic membrane, may portend the presence of cholesteatoma and may require tympanomastoid surgery. Earwax, which may cause reduced hearing (Chapter 396) or ear pain, may be treated with removal of the wax and over-the-counter ceruminolytic agents.

In patients in whom herpes zoster is suspected, acyclovir can be started at 800 mg by mouth five times per day for 7 days, with or without prednisone (Chapter 346). Intracranial complications of otitis media, though rare, require urgent evaluation and surgical intervention.

395 SMELL AND TASTE

ROBERT W. BALOH AND JOANNA C. JEN

EPIDEMIOLOGY

Loss of smell is increasingly being recognized by the fifth decade of life, and an inability to smell or a diminished sense of smell is present in 3 to 20% of the population.[1] Nevertheless, these disorders are often neglected because they are not fatal and, unlike abnormalities of vision and hearing, are not considered serious handicaps. Recently, however, loss of taste and smell has been identified as a common and very bothersome symptom in patients with coronavirus disease 2019 (COVID-19; Chapters 335 to 337),[2] in which changes in smell occur in up to 50% of cases,[3,4] usually several days after the onset of other symptoms

PATHOBIOLOGY

The sensory receptor for taste, the taste bud, is made up of 50 to 150 cells arranged to form a pear-shaped organ. The lifespan of these cells is 10 to 14 days, and they are constantly being renewed from dividing epithelial cells surrounding the bud. Taste buds are located on the tongue, soft palate, pharynx, larynx, epiglottis, uvula, and upper third of the esophagus. The taste buds located on the anterior two thirds of the tongue and on the palate are innervated by the chorda tympani branch of the seventh cranial nerve.[5] The ninth cranial nerve innervates the posterior third of the tongue. The ninth and tenth nerves innervate taste buds in the pharynx and larynx. Afferent signals from the taste buds project to the nucleus of the solitary tract in the medulla and then through a series of relays to the thalamus and postcentral somatosensory cerebral cortex (primary ipsilateral). Free nerve endings of the fifth cranial nerve are found on the tongue and in the oral cavity, and lesions involving these pathways can also alter taste perception.

Olfactory receptors lie in a roughly dime-sized area of specialized pigmented epithelium that arches along the superior aspect of each side of the nasal mucosa. Specialized bipolar sensory cells in this region thrust short receptor hairs into the overlying mucosa to detect aromatic molecules as they dissolve. Like taste buds, the specialized receptor portion of the bipolar neuron undergoes continuous renewal, with turnover occurring approximately every 30 days. Thin axons of the bipolar neurons course through small holes in the cribriform plate of the ethmoid bone to form connections in the overlying olfactory bulb on the ventral surface of the frontal lobe. From there, second- and third-order neurons project directly and indirectly to the prepiriform cortex and parts of the amygdaloid complex of both sides of the brain, which represents the primary olfactory cortex.

Genes that encode chemoreceptor proteins belong to the G protein–coupled receptor superfamily, which accounts for up to 1% of mammalian genomes. Sequence diversity in these genes encodes unique structural motifs that bind to different ligands signaling different odors and tastes. Distinct and dedicated taste receptor cells express unique receptors to detect each of the five basic tastes: sweet (sensed by the heterodimers T1R1 and T1R3), umami (detected by the heterodimers T1R2 and T1R3), bitter (sensed by an estimated 30 T2Rs), sour (sensed by PKD2L1, with membrane-tethered carbonic anhydrase IV sensing carbonation), and salty (epithelial sodium channel). The taste receptor cells transform and transmit information to primary afferents through multiple cranial nerves (VII, IX, and X) that project to the solitary tract nucleus in the brain stem, with relay in the thalamus, and then onward to the primary cortex (Fig. 395-1).

Disorders of taste and smell can be divided into local, systemic, and neurologic categories (Table 395-1). The taste buds and the specialized receptor portion of the bipolar olfactory cells are constantly being renewed, and the process of renewal can be affected by nutritional, metabolic, and hormonal states as well as by therapeutic radiation, drugs, and age. For example, with interruption of mitosis by antiproliferative agents, return of normal taste function takes a minimum of 10 days, whereas return to normal olfactory function takes more than 30 days. Diuretics can block apical ion channels on a taste bud, and antifungal drugs inhibit cytochrome P-450–dependent enzymes at the level of the receptors. Numerous local conditions, such as colds and allergies, chronic sinusitis, and nasal polyposis, can influence the sense of smell by restricting airway patency. Accidental blows to the head can shear the fine axons of the bipolar olfactory neurons and result in loss of smell. Lesions of the fifth, seventh (chorda tympani), and ninth nerves can lead to disordered taste sensation. Kallmann syndrome (Chapter 216) is anosmia associated with male infertility owing to defects in the secretion or action of gonadotropin-releasing hormone. By comparison, the loss of smell and taste in COVID-19 appears to be centrally mediated via immune inflammation.[6]

CLINICAL MANIFESTATIONS

Disorders of taste and smell can cause poor appetite and suboptimal intake of micronutrients, such as zinc, but do not directly contribute to overall protein-calorie undernutrition.[7] Disorders of taste interfere with digestion because taste stimulants alter salivary and pancreatic flow, gastric contractions, and intestinal motility. Smell also contributes to the anticipation and ingestion of food because much of what is tasted is derived from olfactory stimulation during ingestion and chewing. An inability to detect noxious tastes and odors can result in food or gas poisoning, particularly in elderly subjects. In the extreme, chemosensory disorders can lead to overwhelming stress, anorexia, and depression.

DIAGNOSIS

Olfaction can be tested grossly at the bedside with a few easily recognized odors, such as coffee, chocolate, and the roselike aroma of the compound phenylethyl alcohol.[8] Nasal irritants should be avoided. Each nostril is tested separately to determine whether the problem is unilateral or bilateral. Gustatory sensation is typically tested with weak solutions of sugar, salt, and acetic acid or vinegar. The patient must keep the tongue protruded and respond to questions by nodding the head or by pointing to names of the tastes written on cards. The anterior two thirds and posterior third of the tongue should be tested separately.

The most frequently encountered causes of loss of smell are local obstructive disease, viral infections, head injuries (Chapter 368), and normal aging (Chapter 24). Patients can lose their sense of smell not only from chronic allergies and sinusitis[9] (Chapter 394) but also from the nasal sprays and drops that they use to treat these conditions.

The most common causes of loss of the sense of taste are viral infections and drug ingestion, particularly antirheumatic and antiproliferative drugs (see Table 395-1).[10] Many of the systemic disorders that lead to loss of taste probably produce their effect by decreasing the rate of turnover of sensory receptors on the tongue and olfactory epithelia. In pregnancy (Chapter 221), taste is often altered, perhaps because taste buds express receptors for hormones that are altered during pregnancy.

Viral illnesses, such as influenza (Chapter 332), COVID-19 (Chapter 336), viral hepatitis (Chapter 134), and allergic rhinitis, are the most common causes of loss of both taste and smell. Olfactory and gustatory disturbances also can serve as important diagnostic signs for focal neurologic lesions from a neoplastic (e.g., frontal lobe tumors) inflammatory process. Multifocal neurologic disorders such as multiple sclerosis (Chapter 380) and traumatic head injuries (Chapter 368) can affect the central olfactory and gustatory pathways at multiple levels; as a result, abnormalities in taste and smell are common in such patients. Hallucinations of smell and taste occur in persons with epileptogenic lesions affecting the mesial temporal lobe and insular region, respectively. Olfactory disturbances and hallucinations also occur with a number of psychiatric illnesses (particularly depressive illness and schizophrenia), and especially

395 SMELL AND TASTE

ROBERT W. BALOH AND JOANNA C. JEN

EPIDEMIOLOGY

Loss of smell is increasingly being recognized by the fifth decade of life, and an inability to smell or a diminished sense of smell is present in 3 to 20% of the population.[1] Nevertheless, these disorders are often neglected because they are not fatal and, unlike abnormalities of vision and hearing, are not considered serious handicaps. Recently, however, loss of taste and smell has been identified as a common and very bothersome symptom in patients with coronavirus disease 2019 (COVID-19; Chapters 335 to 337),[2] in which changes in smell occur in up to 50% of cases,[3,4] usually several days after the onset of other symptoms

PATHOBIOLOGY

The sensory receptor for taste, the taste bud, is made up of 50 to 150 cells arranged to form a pear-shaped organ. The lifespan of these cells is 10 to 14 days, and they are constantly being renewed from dividing epithelial cells surrounding the bud. Taste buds are located on the tongue, soft palate, pharynx, larynx, epiglottis, uvula, and upper third of the esophagus. The taste buds located on the anterior two thirds of the tongue and on the palate are innervated by the chorda tympani branch of the seventh cranial nerve.[5] The ninth cranial nerve innervates the posterior third of the tongue. The ninth and tenth nerves innervate taste buds in the pharynx and larynx. Afferent signals from the taste buds project to the nucleus of the solitary tract in the medulla and then through a series of relays to the thalamus and postcentral somatosensory cerebral cortex (primary ipsilateral). Free nerve endings of the fifth cranial nerve are found on the tongue and in the oral cavity, and lesions involving these pathways can also alter taste perception.

Olfactory receptors lie in a roughly dime-sized area of specialized pigmented epithelium that arches along the superior aspect of each side of the nasal mucosa. Specialized bipolar sensory cells in this region thrust short receptor hairs into the overlying mucosa to detect aromatic molecules as they dissolve. Like taste buds, the specialized receptor portion of the bipolar neuron undergoes continuous renewal, with turnover occurring approximately every 30 days. Thin axons of the bipolar neurons course through small holes in the cribriform plate of the ethmoid bone to form connections in the overlying olfactory bulb on the ventral surface of the frontal lobe. From there, second- and third-order neurons project directly and indirectly to the prepiriform cortex and parts of the amygdaloid complex of both sides of the brain, which represents the primary olfactory cortex.

Genes that encode chemoreceptor proteins belong to the G protein–coupled receptor superfamily, which accounts for up to 1% of mammalian genomes. Sequence diversity in these genes encodes unique structural motifs that bind to different ligands signaling different odors and tastes. Distinct and dedicated taste receptor cells express unique receptors to detect each of the five basic tastes: sweet (sensed by the heterodimers T1R1 and T1R3), umami (detected by the heterodimers T1R2 and T1R3), bitter (sensed by an estimated 30 T2Rs), sour (sensed by PKD2L1, with membrane-tethered carbonic anhydrase IV sensing carbonation), and salty (epithelial sodium channel). The taste receptor cells transform and transmit information to primary afferents through multiple cranial nerves (VII, IX, and X) that project to the solitary tract nucleus in the brain stem, with relay in the thalamus, and then onward to the primary cortex (Fig. 395-1).

Disorders of taste and smell can be divided into local, systemic, and neurologic categories (Table 395-1). The taste buds and the specialized receptor portion of the bipolar olfactory cells are constantly being renewed, and the process of renewal can be affected by nutritional, metabolic, and hormonal states as well as by therapeutic radiation, drugs, and age. For example, with interruption of mitosis by antiproliferative agents, return of normal taste function takes a minimum of 10 days, whereas return to normal olfactory function takes more than 30 days. Diuretics can block apical ion channels on a taste bud, and antifungal drugs inhibit cytochrome P-450–dependent enzymes at the level of the receptors. Numerous local conditions, such as colds and allergies, chronic sinusitis, and nasal polyposis, can influence the sense of smell by restricting airway patency. Accidental blows to the head can shear the fine axons of the bipolar olfactory neurons and result in loss of smell. Lesions of the fifth, seventh (chorda tympani), and ninth nerves can lead to disordered taste sensation. Kallmann syndrome (Chapter 216) is anosmia associated with male infertility owing to defects in the secretion or action of gonadotropin-releasing hormone. By comparison, the loss of smell and taste in COVID-19 appears to be centrally mediated via immune inflammation.[6]

CLINICAL MANIFESTATIONS

Disorders of taste and smell can cause poor appetite and suboptimal intake of micronutrients, such as zinc, but do not directly contribute to overall protein-calorie undernutrition.[7] Disorders of taste interfere with digestion because taste stimulants alter salivary and pancreatic flow, gastric contractions, and intestinal motility. Smell also contributes to the anticipation and ingestion of food because much of what is tasted is derived from olfactory stimulation during ingestion and chewing. An inability to detect noxious tastes and odors can result in food or gas poisoning, particularly in elderly subjects. In the extreme, chemosensory disorders can lead to overwhelming stress, anorexia, and depression.

DIAGNOSIS

Olfaction can be tested grossly at the bedside with a few easily recognized odors, such as coffee, chocolate, and the roselike aroma of the compound phenylethyl alcohol.[8] Nasal irritants should be avoided. Each nostril is tested separately to determine whether the problem is unilateral or bilateral. Gustatory sensation is typically tested with weak solutions of sugar, salt, and acetic acid or vinegar. The patient must keep the tongue protruded and respond to questions by nodding the head or by pointing to names of the tastes written on cards. The anterior two thirds and posterior third of the tongue should be tested separately.

The most frequently encountered causes of loss of smell are local obstructive disease, viral infections, head injuries (Chapter 368), and normal aging (Chapter 24). Patients can lose their sense of smell not only from chronic allergies and sinusitis[9] (Chapter 394) but also from the nasal sprays and drops that they use to treat these conditions.

The most common causes of loss of the sense of taste are viral infections and drug ingestion, particularly antirheumatic and antiproliferative drugs (see Table 395-1).[10] Many of the systemic disorders that lead to loss of taste probably produce their effect by decreasing the rate of turnover of sensory receptors on the tongue and olfactory epithelia. In pregnancy (Chapter 221), taste is often altered, perhaps because taste buds express receptors for hormones that are altered during pregnancy.

Viral illnesses, such as influenza (Chapter 332), COVID-19 (Chapter 336), viral hepatitis (Chapter 134), and allergic rhinitis, are the most common causes of loss of both taste and smell. Olfactory and gustatory disturbances also can serve as important diagnostic signs for focal neurologic lesions from a neoplastic (e.g., frontal lobe tumors) inflammatory process. Multifocal neurologic disorders such as multiple sclerosis (Chapter 380) and traumatic head injuries (Chapter 368) can affect the central olfactory and gustatory pathways at multiple levels; as a result, abnormalities in taste and smell are common in such patients. Hallucinations of smell and taste occur in persons with epileptogenic lesions affecting the mesial temporal lobe and insular region, respectively. Olfactory disturbances and hallucinations also occur with a number of psychiatric illnesses (particularly depressive illness and schizophrenia), and especially

ABSTRACT

Chemosensory disorders are not life-threatening, but they reduce the enjoyment and quality of life and are very important to patients who have them. Disorders of taste and smell can be divided into local, systemic, and neurologic categories. The most common causes of loss of smell are local obstructive disease, viral infections, head injuries, and normal aging. The most common causes of loss of the sense of taste are viral infections and drug ingestion, particularly antirheumatic and antiproliferative drugs. Drugs known to affect taste or smell should be discontinued if possible to see whether patients improve. Vitamin and mineral therapies have been recommended but are of unproven benefit.

TABLE 395-1 COMMON CAUSES OF LOSS OF TASTE AND SMELL

	TASTE	SMELL
Local	Radiation therapy, oral infections, dentures, dental procedures	Allergic rhinitis, sinusitis, nasal polyposis, upper respiratory infection
Systemic	Cancer, renal failure, hepatic failure, nutritional deficiency (vitamin B_3, zinc), Cushing syndrome, hypothyroidism, diabetes mellitus, infection (viral), drugs (antirheumatic and antiproliferative, e.g., corticosteroids, cisplatin, carboplatin, cyclophosphamide, doxorubicin, and methotrexate)	Renal failure, hepatic failure, nutritional deficiency (vitamin B_{12}), Cushing syndrome, hypothyroidism, diabetes mellitus, infection (viral hepatitis, influenza), drugs (nasal sprays, antihistamines, decongestants, antibiotics, and antirheumatic and antiproliferative drugs that affect taste)
Neurologic	Bell palsy, familial dysautonomia, multiple sclerosis	Head trauma, multiple sclerosis, Parkinson disease, Alzheimer disease, frontal tumor

in patients with depression[11] and in the early stages of many neurodegenerative disorders, including Parkinson disease, motor neuron disease, Huntington disease, Alzheimer dementia,[12] and even mild cognitive impairment.[13]

TREATMENT AND PROGNOSIS

Treatment of olfactory dysfunction secondary to nasal disease is aimed at opening the air passageways while preserving the olfactory epithelium (Chapter 394). Intranasal steroids for rhinosinusitis (Chapter 394),[14] antibiotics as needed for sinusitis, and therapies for seasonal allergies are useful in selected cases,[15] but nasal corticosteroids are not effective for anosmia related to COVID-19.[A1] Drugs known to affect taste or smell (see Table 395-1) should be discontinued for a trial. Vitamin and mineral therapies are of unproven benefit.[A2] The treatment of taste and smell disorders in cancer patients is usually unsatisfactory, and no options are currently supported by firm data.[16] After COVID-19 and other viral infections, smell and taste typically return in 1 to 2 weeks,[17] but some patients have persistent defects.[18] Impaired odor identification, particularly in the anosmic range, is associated with increased mortality in older adults[19] even after controlling for dementia and medical comorbidity.

396 HEARING AND EQUILIBRIUM

ROBERT W. BALOH AND JOANNA C. JEN

DISORDERS OF THE AUDITORY SYSTEM

DEFINITION

The normal ear can detect sound frequencies ranging between 20 and 20,000 Hz; the upper range drops off fairly rapidly with advancing age. The ear is most sensitive between 500 and 4000 Hz, which roughly corresponds to the frequency range most important for understanding speech. The hearing level in this range has several practical implications in terms of the degree of handicap and the potential for useful correction with amplification. A 30- to 40-dB hearing level in the speech range would impair normal conversation, whereas an 80-dB hearing level would make everyday auditory communication almost impossible (the social definition of deafness).

EPIDEMIOLOGY

About 5% of the world population suffers from disabling hearing loss (defined by the World Health Organization as greater than 40 dB in the better hearing ear in adults and greater than 30 dB in the better hearing ear in children). The prevalence of disabling hearing loss is twice as high in poorer countries compared with richer countries. The prevalence increases with every age decade, and it is higher in men than in women across all age decades. Even subclinical hearing loss is independently associated with accelerated cognitive decline, incident cognitive impairment, and a higher risk of accidental injury in community-dwelling older adults.[1,2]

PATHOBIOLOGY

Localization of Lesions within the Auditory Pathways

Conductive hearing loss results from lesions involving the external or middle ear. It is typically characterized by an approximately equal loss of hearing at all frequencies and by well-preserved speech discrimination once the threshold for hearing is exceeded. Patients with conductive hearing loss can hear speech in a noisy background better than in a quiet background because they can understand loud speech as well as anyone.

Sensorineural hearing loss results from lesions of the cochlea or auditory division of the eighth cranial nerve, or both. With sensorineural hearing loss, the hearing levels for different frequencies are usually unequal, typically resulting in better hearing for low- than for high-frequency tones. Patients with sensorineural hearing loss often have difficulty in hearing speech that is mixed with background noise and may be annoyed by loud speech. Three important manifestations of sensorineural lesions are diplacusis, recruitment, and tone decay. Diplacusis and recruitment are common with cochlear lesions; tone decay usually accompanies eighth nerve involvement.

Central hearing disorders result from lesions of the central auditory pathways. As a rule, patients with central lesions do not have impaired hearing for pure tones, and they can understand speech as long as it is clearly spoken in a quiet environment. If the listener's task is made more difficult with the introduction of background noise or competing messages, performance deteriorates more markedly in patients with central lesions than in normal subjects.

DIAGNOSIS

Evaluation

Bedside Test

A quick test for hearing loss in the speech range is to observe the response to spoken commands at different intensities (whisper, conversation, shouting). Tuning fork tests permit a rough assessment of the hearing level for pure tones of known frequency. The clinician can use his or her own hearing level as a reference standard. In the Rinne test, nerve conduction is compared with bone conduction by holding a tuning fork (preferably 512 Hz) against the mastoid process until the sound can no longer be heard. It is then placed 1 inch from the ear and, in normal subjects, can be heard about twice as long by air as by bone. If bone conduction is better than air conduction, the hearing loss is conductive, but care must be taken to ensure that the bone conduction is not heard in the normal ear. In the Weber test, the tuning fork is placed on the patient's forehead or upper teeth. Normally, this sound is referred to the center of the head. If it is referred to the side of unilateral hearing loss, the hearing loss is conductive; if it is referred away from the side of unilateral hearing loss, the loss is sensorineural.

Audiometry

Pure tone testing is the cornerstone of most auditory examinations. Pure tones at selected frequencies are presented through either earphones (air conduction) or a vibrator pressed against the mastoid portion of the temporal bone (bone conduction), and the minimal level that the subject can hear (threshold) is determined for each frequency. Two speech tests are routinely used. The *speech reception threshold* is the intensity at which the patient can correctly repeat 50% of the words presented. The speech reception threshold is a test of hearing sensitivity for speech and should reflect the hearing level for pure tones in the speech range. The *speech discrimination test* is a measure of the patient's ability to understand speech when it is presented at a level that is easily heard. In patients with eighth nerve lesions, speech discrimination scores can be severely reduced, even when pure tone thresholds are normal or nearly normal; by comparison, in patients with cochlear lesions, discrimination tends to be proportional to the magnitude of hearing loss.

Brain stem auditory evoked responses can be recorded from scalp electrodes at 0 to 10 msec (early), 10 to 50 msec (middle), and 50 to 500 msec (late) following a click (a high-frequency stimulus). The early potentials reflect electrical activity at the cochlea, eighth cranial nerve, and brain stem; the later potentials reflect cortical activity. Computer averaging of the responses to 1000 to 2000 clicks separates the evoked potential from background noise. Early evoked responses may be used to estimate the magnitude of hearing loss and to differentiate among cochlea, eighth nerve, and brain stem lesions.

Differential Diagnosis

Conductive Hearing Loss

The history, examination, and audiometry usually provide the key differential features for identifying common causes of hearing loss (Fig. 396-1). Asymmetrical hearing loss in adults is usually idiopathic.[3]

Otosclerosis commonly produces progressive conductive hearing loss by immobilizing the stapes with new bone growth in front of and below the oval window. The hearing loss is typically conductive, although in some persons the cochlea may be invaded by foci of otosclerotic bone, producing an additional sensorineural hearing loss. Otosclerosis usually stabilizes when the hearing level reaches 50 to 60 dB and rarely progresses to deafness.

The most common cause of reversible conductive hearing loss is *impacted cerumen* in the external canal. This benign condition is usually first noticed after bathing or swimming when a droplet of water closes the remaining tiny passageway. The most common serious cause of conductive hearing loss is inflammation of the middle ear, *otitis media*, either infective (suppurative) or noninfective (serous). Chronic otitis media with perforation of the tympanic membrane can result in an invasion of the middle ear and other pneumatized areas of the temporal bone by keratinizing squamous epithelium (*cholesteatoma*). Cholesteatomas can produce erosion of the ossicles and bony labyrinth, thereby resulting in a mixed conductive and sensorineural hearing loss. Barotrauma to the middle ear arises with otalgia and hearing loss and can be associated with serous effusion or hematotympanum (see Fig. 394-15 in Chapter 394). Other causes of conductive hearing loss include trauma, congenital malformations of the external and middle ear, and glomus body tumors.

Sensorineural Hearing Loss

Hereditary Deafness

Genetically determined deafness, usually from hair cell aplasia or deterioration, may be present at birth or may develop in adulthood. The diagnosis of *hereditary deafness* rests on the finding of a positive family history. Mutations in connexin 26, a key component of gap junctions in the inner ear, account for most cases of recessively inherited deafness. *Intrauterine factors* resulting in congenital hearing loss include infection (especially rubella); toxic, metabolic, and endocrine disorders; and anoxia associated with Rh incompatibility and difficult deliveries.

Cochlear Damage

Acute unilateral deafness usually has a cochlear basis. *Bacterial or viral infections* of the labyrinth, *head trauma* with fracture or hemorrhage into the cochlea, or *vascular occlusion* of a terminal branch of the anterior inferior cerebellar artery can extensively damage the cochlea and the vestibular labyrinth. An isolated sudden unilateral sensorineural hearing loss is presumed to reflect a

ABSTRACT

The neural pathways subserving hearing and those most important for equilibrium and spatial orientation are anatomically proximate in much of their course from their end organs in the inner ear to their termination in the superior portion of the temporal lobe. Because of the close anatomic linkage, disorders that affect hearing often affect equilibrium, and vice versa. Nevertheless, substantial pathophysiologic differences make clinical examination of the two systems different. The auditory system is relatively isolated physiologically, so that function and dysfunction can be tested independently of other neural systems. In contrast, the vestibular system has many close physiologic links with other neural systems (particularly the visual-oculomotor, somatosensory, and autonomic systems) and can be difficult to test in isolation of these other systems. Abnormalities of the auditory system lead to only a few well-defined and unique symptoms (i.e., hearing loss or tinnitus). Abnormalities of the vestibular system can mimic disorders of other neural structures when they cause dizziness, visual distortion (oscillopsia), imbalance, nausea, vomiting, and even syncope.

viral infection of the cochlea and auditory nerve terminals. High-dose steroids followed by a rapid taper is recommended (see Treatment).

Sudden unilateral hearing loss often associated with vertigo and tinnitus can result from a *perilymphatic fistula*. Such fistulas may be congenital or may follow stapes surgery or head trauma.

Drugs

Drugs cause acute and subacute bilateral hearing impairment. Salicylates, furosemide, and ethacrynic acid have the potential to produce transient deafness when they are taken in high doses. More toxic to the cochlea are aminoglycoside antibiotics (gentamicin, tobramycin, amikacin, kanamycin, streptomycin, and neomycin). These agents can destroy cochlear hair cells in direct relation to their serum concentrations. Some antineoplastic chemotherapeutic agents, particularly cisplatin, cause severe ototoxicity.

Meniere Disease

Subacute relapsing cochlear deafness occurs with Meniere disease, a condition associated with fluctuating hearing loss and tinnitus, recurrent episodes of abrupt and often severe vertigo, and a sensation of fullness or pressure in the ear. Recurrent endolymphatic hypertension (hydrops) is believed to cause the episodes. On pathologic examination, the endolymphatic sac is dilated, and the hair cells become atrophic. The resulting deafness is subtle and reversible in the early stages but subsequently becomes permanent and is characterized by diplacusis and loudness recruitment. The disorder is usually unilateral, but in about 20 to 40% of patients, bilateral involvement eventually occurs.

Presbycusis

The gradual, progressive, bilateral hearing loss commonly associated with advancing age is called presbycusis. Presbycusis is not a distinct disease entity but rather represents multiple effects of aging on the auditory system. It may include conductive and central dysfunction, although the most consistent effect of aging is on the sensory cells and neurons of the cochlea. The typical audiogram of presbycusis is a symmetrical high-frequency hearing loss gradually sloping downward with increasing frequency. The most consistent pathologic finding associated with presbycusis is degeneration of sensory cells and nerve fibers at the base of the cochlea.

Noise

The recurrent trauma of *noise-induced hearing loss* affects approximately the same region at the base of the cochlea and is also common, particularly among those with exposure to loud explosive or industrial noises. Loud, blaring, modern music has become a recent offender. The loss almost always begins at 4000 Hz and does not affect speech discrimination until late in the disease process. With only brief exposure to loud noise (hours to days), there may be only a temporary threshold shift, but with continued exposure, permanent injury begins. The duration and intensity of exposure determine the degree of permanent injury, but estimates suggest that nearly 25% of American adults have some degree of noise-induced hearing damage or loss.

Acoustic Neuroma

Progressive unilateral hearing loss, which arises insidiously, initially in the high frequencies, and worsens by almost imperceptible degrees, is characteristic of benign neoplasms of the cerebellopontine angle, most commonly *acoustic neuromas*. In about 10% of cases, the hearing loss can be acute, apparently due to either hemorrhage into the tumor or compression of the labyrinthine vasculature. Magnetic resonance imaging (MRI) with contrast enhancement reliably identifies small acoustic neuromas.

Central Hearing Loss

Central hearing loss is unilateral only if it results from damage to the pontine cochlear nuclei on one side of the brain stem from conditions such as *ischemic infarction* of the lateral brain stem (e.g., occlusion of the anterior inferior cerebellar artery [Chapter 376]), a plaque of *multiple sclerosis* (Chapter 380), or, rarely, invasion or compression of the lateral pons by a *neoplasm* or *hematoma* (Chapters 175 and 368). Bilateral *degeneration* of the cochlear nuclei accompanies some of the rare recessive inherited disorders of childhood. As noted, clinically important unilateral hearing loss never results from neurologic disease arising rostral to the cochlear nucleus. Although bilateral hearing loss could, in theory, result from bilateral destruction of central hearing pathways, in practice this is rare because involvement of neighboring structures in the brain stem or hemisphere would usually produce overwhelming neurologic disability.

TREATMENT

If an underlying disorder has not yet destroyed the auditory system and can be ameliorated medically or surgically, hearing may be improved or preserved. Most patients with otosclerosis respond to stapedectomy. Closure of a perilymph fistula may improve hearing. Antibiotic and decongestive treatment of otitis media (Chapter 394) should prevent permanent hearing loss. Removal of ear wax can restore hearing when impacted cerumen is the cause.[4]

A brief course of high-dose steroids is commonly used for patients with idiopathic sudden unilateral sensorineural deafness, but the evidence to support this approach is limited. Intratympanic corticosteroid treatment (four doses of 40 mg/mL of methylprednisolone during 2 weeks) is not inferior to oral treatment (60 mg/day of oral prednisone followed by a 5-day taper) for idiopathic sudden sensorineural hearing loss, and combination oral and intratympanic therapy may be better than either alone.[A1] Hyperbaric oxygen therapy may also be helpful.[A2] A low-salt diet and diuretics are effective in selected cases of Meniere disease.

Folic acid supplementation appears to reduce the rate of hearing loss in the elderly. Hearing aids amplify sound, usually with the goal of making speech intelligible. Patients with conductive hearing loss require simple amplification, but those with sensorineural hearing loss often need frequency-selective amplification to make hearing aids useful. Hearing aids can also blunt the decline in cognitive function in the elderly.[5] Community health care workers can accelerate access to sound amplification devices.[A3]

Cochlear implants can markedly help patients of all ages with profound hearing loss if they have some intact auditory nerve fibers.[6] Intense postoperative speech recognition training is required.

PREVENTION

Noise-induced hearing loss can be prevented with the use of ear plugs and other noise-reducing interventions.[A4] Recent evidence also suggests that ebselen (a glutathione peroxidase 1 mimic at 400 mg twice daily 2 days before and 2 days after a noise challenge) can prevent noise-induced damage.[A5] However, the absence of interventions to blunt age-related hearing loss argues against routine hearing screening even in older adults.[7]

PROGNOSIS

Prognosis depends on the cause of hearing loss. For sudden idiopathic sensorineural hearing loss, about 40% of patients regain hearing but only about 15% have a complete recovery.[8]

TINNITUS

DIAGNOSIS

As many as 10% of U.S. adults may complain of tinnitus. The evaluation of common causes of tinnitus (Fig. 396-2) begins with a careful history to identify common offending drugs.[9]

Objective Tinnitus

With objective tinnitus, the patient hears a sound arising external to the auditory system, a sound that can usually be heard by the examiner with a stethoscope. Objective tinnitus usually has benign causes, such as noise from temporomandibular joints, opening of eustachian tubes, or repetitive muscle contractions. Sometimes, in a quiet room, the patient can hear the pulsatile flow in the carotid artery or a continuous hum of normal venous outflow through the jugular vein. The latter can be obliterated by compression of the jugular vein or extreme lateral rotation of the neck. Pathologic objective tinnitus occurs when patients hear turbulent flow in vascular anomalies or tumors (e.g., glomus jugulare tumor). Objective tinnitus also may be an early sign of increased intracranial pressure. Such tinnitus, which probably arises from turbulent flow through compressed venous structures at the base of the brain, is usually overshadowed by other neurologic abnormalities.

Subjective Tinnitus

Subjective tinnitus can arise from sites anywhere in the auditory system. The sounds most frequently reported are metallic ringing; buzzing; blowing; roaring; or, less often, bizarre clanging, popping, or nonrhythmic beating. Tinnitus heard as a faint, moderately high pitched, metallic ring can be observed by almost anyone who concentrates attention on auditory events in a quiet room. Sustained louder tinnitus accompanied by audiometric evidence of deafness occurs in association with both conductive and sensorineural hearing loss. Tinnitus observed with otosclerosis tends to have a roaring or hissing quality, and that associated with Meniere disease often produces sounds that vary widely in intensity with time and quality, sometimes including roaring or clanging. Tinnitus with auditory nerve lesions tends to be higher pitched and ringing in quality. Audiometric and brain stem evoked response testing can help distinguish between lesions involving the conducting apparatus, the cochlea, and the auditory nerve. Tinnitus without observable deafness appears sporadically and for variable lengths of time in many persons without other evidence of an ongoing pathologic process.

TREATMENT

Most patients with tinnitus can be helped by a careful evaluation to exclude serious underlying conditions and by subsequent reassurance when appropriate.[10] Often, exacerbating factors such as chronic anxiety and depression can be treated. In patients with hearing loss and tinnitus, a hearing aid may improve tinnitus because the amplification of ambient sound may effectively mask the tinnitus. This mechanism probably explains the frequent observation that removal of cerumen from the external auditory canal to improve ambient hearing also improves tinnitus. Also, when cerumen is attached to the tympanic membrane, tinnitus may result from local mechanical effects on the conductive system. For patients who find their tinnitus most obtrusive when trying to sleep, recorded masking sounds (e.g., white noise, rainfall, mountain stream) can be helpful. A careful drug history should be taken (see Fig. 396-2), and a drug-free trial period should be considered when possible.

No medications are approved for the treatment of tinnitus in the United States or Europe. Benzodiazepines (e.g., diazepam, 2 to 5 mg every 8 hours) or tricyclic amines (e.g., amitriptyline, 25 to 75 mg at bedtime) may provide temporary symptomatic relief of tinnitus, but cognitive-behavioral therapy, which can be administered face-to-face or via the Internet, is a more effective long-term approach that can significantly decrease tinnitus and improve health-related quality of life,[A6,A7] and group cognitive behavioral treatment may be better than individual therapy.[A8] Furthermore, some patients have varying degrees of spontaneous improvement. In patients with concomitant profound bilateral sensorineural hearing loss, cochlear implants can improve hearing and often decrease tinnitus.

EQUILIBRIUM–VESTIBULAR SYSTEM

PATHOBIOLOGY

Anatomy and Physiology of the Vestibular System

The paired vestibular end organs lie within the temporal bones next to the cochlea. Each organ consists of three semicircular canals that detect angular acceleration and two otolith structures, the utricle and saccule, that detect linear acceleration (including gravitational). Like the cochlea, these organs possess hair cells that act as force transducers, converting the forces associated with head acceleration into afferent nerve impulses. The hair cells of the three semicircular canals, each of which is oriented at right angles to the others, are located in the crista, where their cilia are embedded in a gelatinous mass called the *cupula*. Movement of the head causes the endolymph to flow either toward or away from the cupula, bending the cilia and, depending on the direction of endolymphatic movements, either exciting or inhibiting the afferent nerves at the base of the hair cells. The hair cells of the utricle and saccule are located in an area called the *macule*. The macule of the utricle lies approximately in the plane of the horizontal canal, and the macule of the saccule is approximately in the plane of the anterior canal. The hair cell cilia are embedded in a membrane that contains calcium carbonate crystals or otoliths; the density of otoliths is considerably greater than that of the endolymph. Linear accelerations of the head combine with the linear acceleration of gravity to distort the otolith membrane, thereby bending the cilia of the hair cells and modulating the activity of the afferent nerve terminals at the base of the hair cells.

The afferent vestibular nerves have their cell bodies in the Scarpa ganglion. The nerve fibers travel in the vestibular portion of the eighth cranial nerve contiguous to the acoustic portion. Fibers from different receptor organs terminate in different vestibular nuclei at the pontomedullary junction. There are also direct connections with many portions of the cerebellum, the greatest representation being in the flocculonodular lobe, the so-called vestibular cerebellum.

DIAGNOSIS

Evaluation

History

Most vestibular problems presented to the physician are episodic, and often there are neither symptoms nor signs when the physician examines the patient. The history therefore can become paramount for identifying vestibular dysfunction. The history should attempt to distinguish vertigo (the illusion of movement in space) from other types of dizziness (see later).

About 12% of patients with vertigo have a central cause, and about 88% have a problem with the peripheral vestibular apparatus. In general, peripheral vertigo is more severe, is more likely to be associated with hearing loss and tinnitus, and often leads to nausea and vomiting. Nystagmus associated with peripheral vertigo is usually inhibited by visual fixation. Central vertigo is generally less severe than peripheral vertigo and is often associated with other signs of central nervous system disease.[11] The nystagmus of central vertigo is not inhibited by visual fixation and frequently is prominent when vertigo is mild or absent.

Common Causes of Vertigo

Physiologic Vertigo

Physiologic vertigo includes common disorders that occur in healthy people, such as *motion sickness, space sickness,* and *height vertigo* (Fig. 396-3). In these conditions, vertigo (defined as an illusion of movement) is minimal whereas autonomic symptoms predominate. With height vertigo, patients may experience acute anxiety and panic reaction. Individuals with motion sickness and space sickness typically develop perspiration, nausea, vomiting, increased salivation, yawning, and generalized malaise. Gastric motility is reduced and digestion impaired. Even the sight or smell of food is distressing. Hyperventilation is a common sign, and the resulting hypocapnia leads to changes in blood volume, with pooling in the lower parts of the body predisposing to postural hypotension and syncope. An unusual variant of motion-induced dizziness occurs when the subject returns to stationary conditions after prolonged exposure to motion *(mal de débarquement syndrome)*. Typically, affected patients report that they feel the persistent rocking sensation of a boat long after returning to solid ground. Rarely, the syndrome can last for months to years after exposure to motion and can even be incapacitating. The cause is unknown.

Physiologic vertigo often can be suppressed by supplying sensory cues that help to match the signals originating from different sensory systems. Thus, motion sickness, which is caused by a mismatch of visual and vestibular signals, is exacerbated by sitting in a closed space or reading (giving the visual system the miscue that the environment is stationary). It may be improved by looking out at the horizon. Height vertigo, caused by a mismatch between sensation of normal body sway and lack of its visual detection, often can be relieved either by sitting or by visually fixating on a nearby stationary object.

Benign Paroxysmal Positional Vertigo (Canalithiasis)

Benign paroxysmal positional vertigo is by far the most common cause of vertigo.[12] Patients with this condition develop brief episodes of vertigo (<1 minute) with position change, typically when turning over in bed, getting in and out of bed, bending over and straightening up, or extending the neck to look up (so-called top-shelf vertigo). Benign paroxysmal positional vertigo results when otolith debris inadvertently enters one of the semicircular canals. It can occur after head trauma or inner ear infection but most commonly occurs spontaneously in older people and particularly in older women with osteoporosis. The diagnosis rests on finding characteristic positional nystagmus in the plane of the affected canal (see later). It is important to recognize this syndrome because, in most patients, it can be cured by simple bedside maneuvers (Fig. 396-4). If the history or findings are atypical, the condition must be distinguished from other causes of positional vertigo that may occur with tumors or infarcts of the posterior fossa.

Acute Peripheral Vestibulopathy (Vestibular Neuritis)

One of the most common clinical neurologic syndromes at any age is the acute onset of vertigo, nausea, and vomiting lasting for several days and not

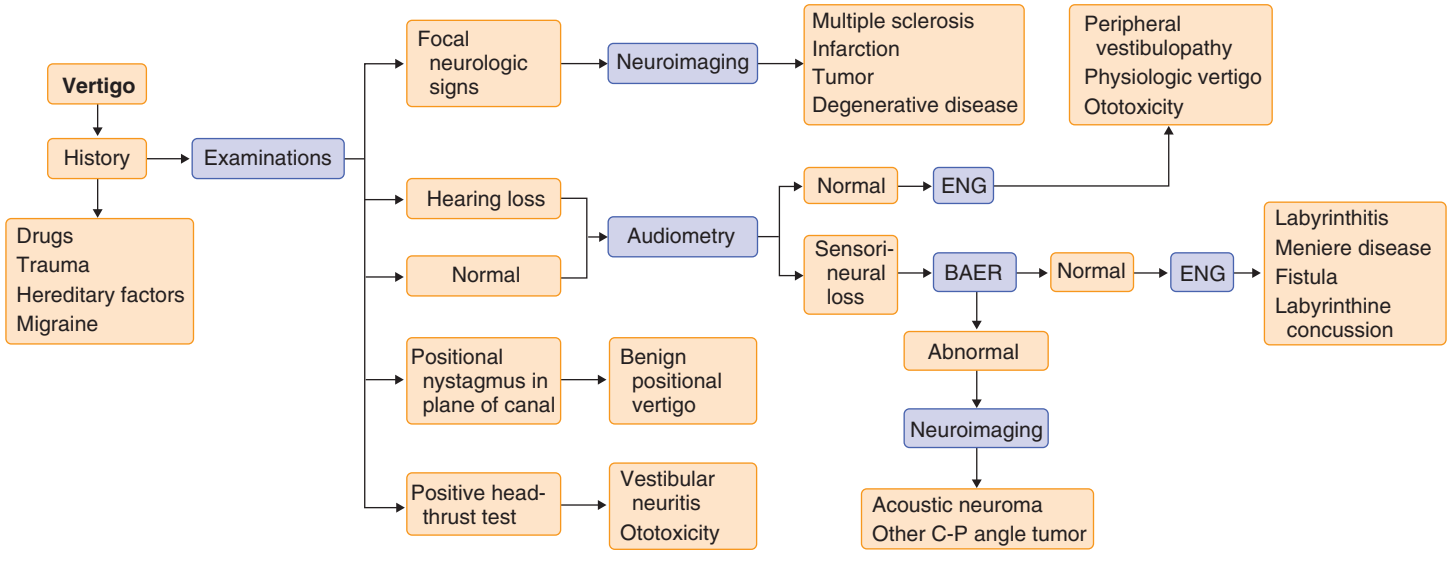

FIGURE 396-3. **Evaluation of vertigo.** BAER = brain stem auditory evoked response; C-P = cerebellopontine; ENG = electronystagmography.

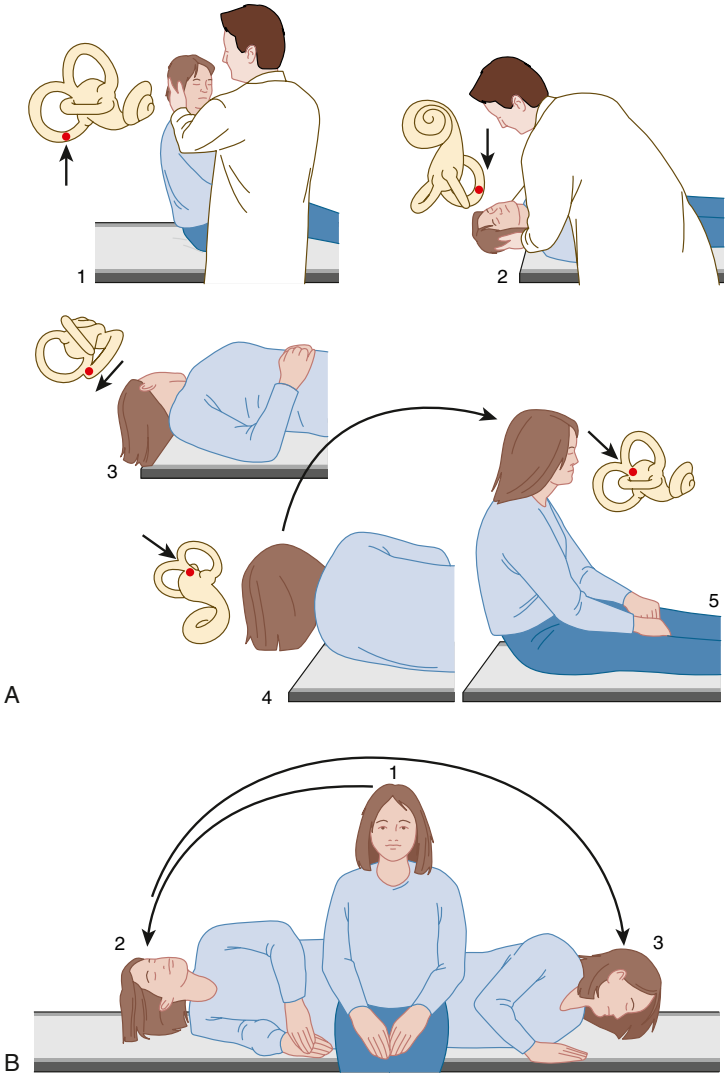

FIGURE 396-4. Modified Epley (A) and Semont (B) maneuvers for benign positional vertigo affecting the right posterior semicircular canal. The procedure is reversed to treat the left posterior semicircular canal. The entire sequence should be repeated until no nystagmus is elicited. (From Fife TD, Iverson DJ, Lempert T, et al. Practice parameter: therapies for benign paroxysmal positional vertigo [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2008;70:2067-2074.)

associated with auditory or neurologic symptoms. A viral origin is suspected, but attempts to isolate an agent have been unsuccessful, except for occasional findings of a herpes zoster infection. Pathologic studies showing atrophy of one or more vestibular nerve trunks, with or without atrophy of their associated sense organs, are evidence of a vestibular nerve site and, probably, viral cause for most patients with this syndrome. Patients gradually improve during 1 to 2 weeks, but residual dizziness and imbalance can persist for months.

Meniere Disease

Meniere disease (see earlier) accounts for about 10% of all patients with vertigo. The diagnosis is based on documenting episodic severe attacks accompanied by fluctuating hearing levels on audiometric testing beginning in the low frequencies.

Migraine

Vertigo is a common symptom with migraine (Chapter 367). It can occur with headaches or in separate isolated episodes, and it can predate the onset of headache. So-called benign paroxysmal vertigo of childhood is often the first symptom of migraine. The mechanism of vertigo with migraine is not clear, but both peripheral and central types of nystagmus can occur with attacks. A few develop typical features of Meniere disease.

Post-traumatic Vertigo

Vertigo, hearing loss, and tinnitus often follow a blow to the head (Chapter 368) that does not result in temporal bone fracture, termed *labyrinthine concussion*. Blows to the occipital or mastoid region are particularly likely to produce labyrinthine damage. *Transverse fractures* of the temporal bone typically pass through the vestibule of the inner ear, tearing the membranous labyrinth and lacerating the vestibular and cochlear nerves. Complete loss of vestibular and cochlear function is the usual sequela, and the facial nerve is interrupted in approximately 50% of cases. Examination of the ear often reveals hemotympanum (see Fig. 394-15 in Chapter 394), but bleeding from the ear seldom occurs because the tympanic membrane usually remains intact. As noted earlier, *benign paroxysmal positional vertigo* is also a common sequela of head trauma. *Fistulas* of the oval and round windows can result from impact noise, deep-water diving, severe physical exertion, or blunt head injury without skull fracture. Clinically, the rupture leads to the sudden onset of vertigo or hearing loss, or both. Surgical exploration of the middle ear is warranted when there is a clear relationship between the onset of vertigo or hearing loss, or both, and the onset of severe exertion, barometric change, head injury, or impact noise.

Postconcussion Syndrome

The so-called postconcussion syndrome refers to a vague dizziness (not vertigo) associated with anxiety, difficulty in concentrating, headache, and photophobia induced by a head injury resulting in concussion (Chapter 368). On occasion, similar but less pronounced symptoms are associated with mild head injury judged to be trivial at the time. The cause is unknown, but animal studies indicate that small multifocal brain lesions (petechiae) commonly occur after concussive brain injury.

Other Peripheral Causes of Vertigo

Vertigo can be associated with *chronic bacterial otomastoiditis*, either from direct invasion of the inner ear by the bacteria or by erosion of the labyrinth by a cholesteatoma. Radiographic studies of the temporal bone readily identify these disorders. *Autoimmune inner ear disease* typically arises with episodic vertigo and fluctuating hearing levels similar to Meniere disease, but it is more fulminant with early bilateral involvement. It can occur in isolation or with other systemic features of autoimmune disease. About two thirds of patients have antibodies directed against heat shock protein 70. The aminoglycosides streptomycin and gentamicin are remarkably selective for vestibular ototoxicity. The patient may suffer acute vertigo if the toxic effect is asymmetrical. More often, there is a progressive symmetrical loss of vestibular function leading to imbalance but not vertigo. Unfortunately, many patients being treated with ototoxic drugs are initially bedridden and unaware of the vestibular impairment until they recover from their acute illness and try to walk. They then discover that they are unsteady on their feet and that the environment tends to jiggle in front of their eyes *(oscillopsia)*. The diagnosis can be made at the bedside with a head-thrust test (bilateral corrective saccades; see later). Caloric and rotational testing can confirm the vestibular loss. The best treatment is prevention. If the drug is discontinued early during the course of symptoms, the disorder may stabilize or improve.

Vascular Insufficiency

Vertebrobasilar insufficiency is a common cause of vertigo in older people. Whether the vertigo originates from ischemia of the labyrinth, brain stem, or both structures is not always clear because the blood supplies to the labyrinth, eighth cranial nerve, and vestibular nuclei originate from the same source, the basilar vertebral circulation (Chapter 375). Vertigo with *vertebrobasilar insufficiency* is abrupt in onset, usually lasting several minutes, and is frequently associated with nausea and vomiting. Associated symptoms resulting from ischemia in the remaining territory supplied by the posterior circulation include visual illusions and hallucinations, drop attacks and weakness, visceral sensations, visual field defects, diplopia, and headache. These symptoms occur in episodes either in combination with the vertigo or alone. Vertigo may be an isolated initial symptom of vertebrobasilar ischemia, but repeated episodes of vertigo without other symptoms should suggest another diagnosis. Vertebrobasilar insufficiency is usually caused by atherosclerosis of the subclavian, vertebral, and basilar arteries. MRI of the brain is usually normal because the vascular insufficiency is transient and function returns to normal between episodes. Magnetic resonance angiography can identify occlusive vascular disease most commonly involving the vertebral-basilar junction.

Vertigo is a common symptom with *infarction of the lateral brain stem* or *cerebellum* (Chapter 376), or both. The diagnosis is usually clear, based on the characteristic acute history and pattern of associated symptoms and neurologic findings. On occasion, cerebellar infarction or hemorrhage arises with

severe vertigo, vomiting, and ataxia without associated brain stem symptoms and signs that might suggest the erroneous diagnosis of an acute peripheral vestibular disorder. The key differential is the finding of clear cerebellar signs (extremity and gait ataxia); direction-changing, gaze-evoked nystagmus; and a normal head-thrust test. Such patients must be watched carefully for several days because they may develop progressive brain stem dysfunction as a result of compression by a swollen cerebellum.

Cerebellopontine Angle Tumors

Most tumors growing in the cerebellopontine angle (e.g., *acoustic neuroma, meningioma, epidermal cyst*) grow slowly, allowing the vestibular system to accommodate so that they produce only a vague sensation of disequilibrium rather than acute vertigo (Chapter 175). On occasion, however, episodic vertigo or positional vertigo heralds the presence of a cerebellopontine angle tumor. In virtually all patients, retrocochlear hearing loss is present, best identified by audiometric testing. MRI with contrast enhancement is the most sensitive diagnostic study for identifying a cerebellopontine angle tumor.

Other Central Causes of Vertigo

Acute vertigo may be the first symptom of *multiple sclerosis* (Chapter 380), although only a small percentage of young patients with acute vertigo eventually develop multiple sclerosis. Vertigo in multiple sclerosis is usually transient and often associated with other neurologic signs of brain stem disease, in particular, internuclear ophthalmoplegia or cerebellar dysfunction. Vertigo also may be a symptom of *parainfectious encephalomyelitis* or, rarely, *parainfectious cranial polyneuritis*. In this instance the accompanying neurologic signs establish the diagnosis. The *Ramsay Hunt syndrome* (geniculate ganglion herpes) is characterized by vertigo and hearing loss associated with facial paralysis and, sometimes, pain in the ear. The typical lesions of herpes zoster (Chapter 346), which may follow the appearance of neurologic signs, are found in the external auditory canal and over the palate in some patients. Rarely is herpes zoster responsible for vertigo in the absence of the full-blown syndrome. *Granulomatous meningitis* (Chapter 381) or *leptomeningeal metastasis* and cerebral or systemic *vasculitis* (Chapter 249) may involve the eighth nerve, producing vertigo as an early symptom. In these disorders, cerebrospinal fluid analysis usually suggests the diagnosis (Chapter 366). Patients suffering from *temporal lobe epilepsy* (Chapter 372) occasionally experience vertigo as the aura. Vertigo in the absence of other neurologic signs or symptoms is never caused by epilepsy or other diseases of the cerebral hemispheres.

Bedside Tests

Hyperventilation

If the history is not clear, bedside provocative tests to mimic the symptom may assist in making a pathophysiologic diagnosis. Hyperventilation, which lowers the arterial partial pressure of carbon dioxide ($Paco_2$) and decreases cerebral blood flow, causes a lightheaded sensation associated with syncope. Patients with compressive lesions of the vestibular nerve, such as with an acoustic neuroma or cholesteatoma, or with demyelination of the vestibular nerve root entry zone may develop vertigo and nystagmus after hyperventilation. Presumably, metabolic changes associated with hyperventilation trigger the partially damaged nerve to fire inappropriately.

Vestibulospinal Function

Bedside tests of vestibulospinal function are often insensitive because most patients can use vision and proprioceptive signals to compensate for any vestibular loss. Patients with acute unilateral peripheral vestibular lesions may past-point or fall toward the side of the lesion, but within a few days, balance returns to normal. Patients with bilateral peripheral vestibular loss have more difficulty compensating and usually show some imbalance on the Romberg and tandem walking tests (Chapter 366), particularly with eyes closed.

Doll's-Eye and Head-Thrust Tests

The vestibulo-ocular reflex can be tested at the bedside with the doll's-eye and head-thrust tests. In an alert human, rotating the head back and forth in the horizontal plane induces compensatory horizontal eye movements that are dependent on both the visual and vestibular systems. The doll's-eye test is a test of vestibular function in a comatose patient (Chapter 373) because such patients cannot generate pursuit or corrective fast components. In this setting, conjugate compensatory eye movements indicate normally functioning vestibulo-ocular pathways. Because the vestibulo-ocular reflex has a much higher frequency range than the smooth pursuit system, a qualitative bedside test of vestibular function can be made with the *head-thrust test*. It is performed by grasping the patient's head and applying brief, small-amplitude, high-acceleration head thrusts first to one side and then the other. The patient fixates on the examiner's nose and the examiner watches for corrective saccades, which are a sign of an inappropriate compensatory slow phase.

Caloric Test

The caloric test induces endolymphatic flow in the horizontal semicircular canal and horizontal nystagmus by creating a temperature gradient from one side of the canal to the other. With a cold caloric stimulus, the column of endolymph nearest the middle ear falls because of its increased density. This causes the cupula to deviate away from the utricle (ampullofugal flow) and produces horizontal nystagmus with the fast phase directed away from the stimulated ear. A warm stimulus produces the opposite effect, causing ampullopetal endolymph flow and nystagmus directed toward the stimulated ear (a mnemonic is COWS, meaning cold opposite, warm same). Because of its ready availability, ice water (approximately 0° C) can be used for bedside caloric testing. To bring the horizontal canal into the vertical plane, the patient lies in the supine position with head tilted 30 degrees forward. Infusion of 1 to 3 mL of ice water induces a burst of nystagmus usually lasting about a minute. Greater than a 20% asymmetry in nystagmus duration suggests a lesion on the side of the decreased response. The ice water caloric test is a useful way to test the integrity of the oculomotor pathways in a comatose patient. In this case ice water induces only a slow tonic deviation toward the side of stimulation.

Positional Tests

Examination for pathologic vestibular nystagmus should include a search for spontaneous and positional nystagmus (see Table 392-4 in Chapter 392). Because vestibular nystagmus secondary to peripheral vestibular lesions is inhibited with fixation, the yield is increased by impairing fixation with +30 lenses (Frenzel glasses) or infrared video recordings. Two types of positional testing are typically performed: moving the patient from the sitting to head-hanging-right and head-hanging-left positions (Dix-Hallpike test) and turning the head to the right and left while the patient lies supine.[13] Induced positional nystagmus may be paroxysmal or persistent, and it may be in the same direction in all positions or change directions in different positions. The most common cause of positional nystagmus is otolith debris in the semicircular canals, either free floating (paroxysmal) or attached to the cupula (persistent). This type of nystagmus always occurs in the plane of the affected canal—vertical torsional for the vertical canals and horizontal torsional for the horizontal canal. By contrast, central positional nystagmus is often pure vertical or horizontal and cannot be explained by stimulating a single semicircular canal.

Nystagmography

Nystagmography tests oculomotor control by inducing and recording eye movements. A standard test battery includes (1) tests of visual ocular control (saccades, smooth pursuit, and optokinetic nystagmus), (2) a careful search for pathologic nystagmus with fixation and with eyes open in darkness, and (3) the measurement of induced vestibular nystagmus (caloric and rotational). Nystagmography can be helpful in identifying a vestibular lesion and localizing it within the peripheral and central pathways.

Evaluating the "Dizzy" Patient

The history is key because it determines the type of dizziness (Table 396-1 and see Fig. 396-3), associated symptoms (neurologic, audiologic, cardiac, psychiatric), precipitating factors (position change, trauma, stress, drug ingestion), and predisposing illness (systemic viral infection, cardiac disease, cerebrovascular disease). The history provides direction for both the examination and the diagnostic evaluation. When focal neurologic signs are found, neuroimaging usually leads to a specific diagnosis. When vertigo is present without focal neurologic symptoms or signs, head-thrust and positional testing are key to localizing the lesion to the labyrinth or eighth nerve.[14] Audiometry and nystagmography are useful if the cause of vertigo is not clear after the history and examination. Patients with psychogenic dizziness (also called chronic subjective dizziness or persistent perceptual-postural dizziness) should be identified early so that needless tests are not obtained. A detailed cardiac evaluation (including loop monitoring) often identifies the cause of episodic near-fainting (Chapters 39 and 49). Experimental miniature video-oculography goggles can record spontaneous and positional nystagmus during a vertiginous attack and help distinguish among benign paroxysmal positional vertigo, Meniere disease, and vestibular migraines.[15]

TABLE 396-1 DESCRIPTION, MECHANISM, AND FOCUS OF DIAGNOSTIC WORK-UP FOR COMMON TYPES OF DIZZINESS

TYPE OF DIZZINESS	DESCRIPTION	MECHANISM	FOCUS OF DIAGNOSTIC EVALUATION
Vertigo	Spinning (environment moves), tilt, drunkenness	Imbalance in tonic vestibular activity	Auditory and vestibular systems
Near-faint	Lightheaded, swimming	Decreased blood flow to entire brain	Cardiovascular system
Psychogenic	Dissociated from body, spinning inside (environment still)	Impaired central integration of sensory signals	Psychiatric assessment
Disequilibrium	Off balance, unsteady on feet	Loss of vestibulospinal, proprioceptive, cerebellar, or motor function	Neurologic assessment

TREATMENT

Treatment of vertigo can be divided into three general categories: specific, symptomatic, and rehabilitative. When possible, treatment should be directed at the underlying disorder (Table 396-2). Specific therapies include particle repositioning maneuvers (the Epley and Semont maneuvers; see Fig. 396-4) for benign paroxysmal positional vertigo.[A9] For vestibular neuritis, steroids (e.g., methylprednisolone, 1 mg/kg/day for 5 days, then tapered during the next 15 days) are effective, at least for the short term, but antiviral agents are not. For Meniere disease, a low-salt diet and diuretics (e.g., 25 mg hydrochlorothiazide and 50 mg triamterene daily) are effective in some cases. Intratympanic methylprednisolone is comparable to intratympanic gentamicin injection in reducing vertiginous attacks in patients with refractory unilateral Meniere disease, but methylprednisolone preserves hearing.[A10] Endolymphatic duct blockage is a potential option for medically refractory Meniere disease. Limited data suggest that vitamin D (400 IU daily) plus calcium carbonate (500 mg twice daily) may reduce the risk of recurrent vertigo by about 25% in individuals who have benign paroxysmal positional vertigo and low vitamin D levels,[A11] but the findings of this single-blind trial require confirmation.

In many cases, however, symptomatic treatment either is combined with specific therapy or is the only treatment available. Many different classes of drugs have been found to have antivertiginous properties, and in most instances, the exact mechanism of action is uncertain. All these agents produce potentially unpleasant side effects, and the decision concerning which drug or combination to use is based on their known complications and on the severity and duration of the vertigo. An episode of prolonged, severe vertigo is one of the most distressing symptoms that a patient can experience. Affected patients prefer to lie still with eyes closed in a quiet, dark room. Antivertiginous drugs, such as dimenhydrinate (25 mg) or diazepam (5 mg), may be helpful. Promethazine suppositories (25 mg) are useful in patients with vomiting.

In more chronic vertiginous disorders, when the patient is trying to carry on normal activity, less sedating antivertiginous medications, such as meclizine (25 mg) or transdermal scopolamine (0.5 mg every 3 days), may provide relief. Chronic use of these drugs should be avoided.

Vestibular rehabilitation exercises are designed to help the patient compensate for permanent loss of vestibular function.[A12] As the acute stage of nausea and vomiting subsides, the patient should attempt to focus the eyes and to move and hold them in the direction that provokes the most dizziness. A useful exercise involves staring at a visual target while oscillating the head from side to side or up and down, slow at first and then fast. The patient should try to stand and walk, at first in contact with a wall or with an assistant, and make slow supported turns. As improvement occurs, head movements should be added while standing and walking. For refractory ototoxic or idiopathic chronic bilateral vestibular hypofunction, a vestibular implant that electrically stimulates the vestibular nerve is an experimental approach to improve posture, gait, and quality of life, although it may reduce hearing in the ear with the implant.[16]

PROGNOSIS

Vertigo commonly resolves, either because patients become truly asymptomatic or adjust to occasional symptoms. Among patients diagnosed with a peripheral cause of vertigo, the 30-day risk of accidental injury is less than 0.2%, as is the 30-day risk of stroke.

TABLE 396-2 TREATMENT OF COMMON VERTIGO SYNDROMES

SYNDROME	TREATMENT
Benign positional vertigo	
Posterior canal variant	Epley maneuver (see Fig. 396-4)
Horizontal canal variant	Barbecue roll toward normal side (side with less nystagmus), sleep with normal ear down
Vestibular neuritis	Methylprednisolone, 100 mg × 3 days, gradual taper during 22 days (must start within 3 days of onset)
Meniere disease	
Medical	Low salt (1-2 g salt/day) *and* either hydrochlorothiazide 25-50 mg/day *or* hydrochlorothiazide 25 mg/day plus triamterene 50 mg/day
Surgical	Intratympanic gentamicin, vestibular nerve section

397 THROAT DISORDERS

PAUL W. FLINT

Nearly every systemic and infectious disease results in head and neck manifestations, with the majority affecting the upper aerodigestive tract. Diseases of the upper aerodigestive system include infection (acute and chronic; viral, bacterial, and fungal), systemic disease, and neoplasm (Chapter 176), some of which require urgent care or referral to an otolaryngologist.[1]

Abnormalities of swallowing, respiratory function, voice, and speech are influenced by the anatomic site involved, the host's immune status and inflammatory response, the severity of the disease process, and the presence or absence of neurologic involvement.

In a patient with hoarseness, current clinical practice guidelines recommend visualization of the larynx for symptoms that persist for 3 months or longer; however, warning signs of a potentially serious or emergent throat condition warrant referral regardless of duration. These conditions include persistent throat pain with or without trismus, difficulty in swallowing, difficulty in breathing, hemoptysis, and ear pain with normal ear examination findings. Diagnostic testing options, which include fiberoptic examination, imaging, pulmonary function studies, and laboratory testing, are directed by history, symptoms, and physical findings.

ANATOMY OF THE UPPER AERODIGESTIVE TRACT

The pharynx is divided into three anatomic regions (Fig. 397-1). The *nasopharynx* is the region above the soft palate and uvula. Its anatomic components include the adenoids, the openings of the eustachian tubes, Rosenmüller fossa at the junction of the posterior and lateral walls, and the posterior aspect of the inferior turbinates of the nasal cavity. Diseases of the nasopharynx typically produce few symptoms until the process is well advanced and causes nasal obstruction (Chapter 394), epistaxis (Chapter 394), ear pain (Chapter 394), headache (Chapter 367), or cranial nerve abnormalities due to extension to the skull base. The *oropharynx* begins at the level of the soft palate and extends inferiorly to the tip of the epiglottis. This region includes the faucial tonsils, the base of the tongue, the lingual tonsils, the soft palate, the uvula, and part of the posterior pharyngeal wall. The *hypopharynx*, which extends from the tip of the epiglottis to the upper esophagus (the cricopharyngeus muscle) below, includes the larynx (epiglottis, arytenoids, glottis or true vocal cords), the piriform sinuses (pharyngeal folds lateral to the larynx), and the posterior pharyngeal wall. The tip of the epiglottis can be visualized by an experienced examiner with use of a laryngeal mirror or sometimes even on a routine oral examination with just a flashlight and tongue blade. The nasopharynx and hypopharynx are best visualized with a flexible fiberoptic nasopharyngoscope.

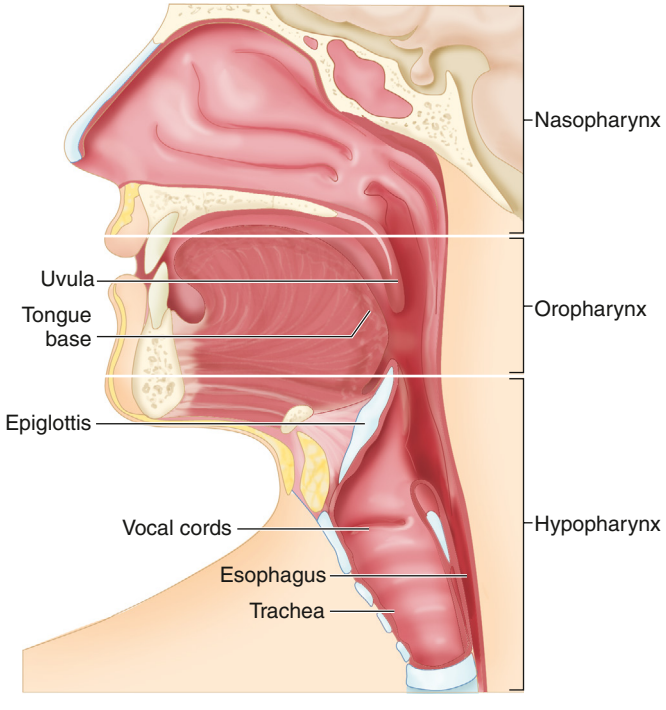

FIGURE 397-1. The pharynx (throat) is typically divided into three distinct anatomic regions (nasopharynx, oropharynx, and hypopharynx). (Courtesy Thomas A. Tami, MD.)

INFECTIOUS DISEASES OF THE UPPER AERODIGESTIVE SYSTEM

Infectious disorders of the upper aerodigestive tract typically are manifested as sore throat (pharyngitis),[2] changes in voice (laryngitis), or both.[3] The clinical evaluation must differentiate among bacterial (usually streptococcus [Chapter 269]), viral, and other infections and systemic causes (Table 397-1). Clinical differentiation of sore throat is critical to primary care and emergency management of the airway.

PHARYNGITIS

Bacterial infection accounts for approximately 5 to 10% of pharyngitis in adults compared with 30 to 40% in children. Unfortunately, as many as two thirds of adults with a sore throat are prescribed antibiotics.

STREPTOCOCCAL INFECTIONS

Group A β-hemolytic *Streptococcus pyogenes* (Chapter 269) is the most common cause of bacterial pharyngitis in adults, although it accounts for only 10% of all pharyngitis in adults. Infection is manifested with the rapid onset of sore throat, often accompanied by pain with swallowing, fever, chills, malaise, headache, mild neck stiffness, and anorexia. Hypertrophic tonsils with exudates, foul breath, and tender cervical adenopathy are hallmark findings. Some patients have palatal petechiae or a scarlatiniform rash. Rhinorrhea, hoarseness, cough, conjunctivitis, diarrhea, and ulcerative oral lesions are less common.

Untreated group A β-hemolytic *S. pyogenes* pharyngitis usually resolves within 3 to 7 days. The administration of antibiotics within 24 to 48 hours reduces pain by approximately 1 day,[A1] whereas both immediate and delayed antibiotics reduce the risk for suppurative complications.[A2] Antibiotics also reduce the contagious period from 2 weeks to 24 hours after administration. For prevention of rheumatic fever (Chapter 269), antibiotic therapy must be started within 10 days after the onset of symptoms. The risk for acute poststreptococcal glomerulonephritis (Chapter 107), however, is not affected by antibiotics.

To minimize the potential side effects and costs of unnecessary antibiotics, antibiotic therapy should be based on the presence of fever, tender anterior cervical adenopathy, tonsillar swelling or exudates, age, and the absence of cough. A rapid antigen test should be obtained in patients with three or more (or perhaps two or more) criteria (Table 397-2).[4] If the rapid antigen test result is negative but the clinical suspicion remains high, a throat culture specimen should be obtained for confirmation before starting antibiotics. Such a strategy can significantly reduce the unnecessary use of antibiotics.[A3]

Antibiotic options (Chapter 269) include penicillin (penicillin VK, 250 mg four times a day or 500 mg twice a day for 10 days), which is usually chosen to treat acute bacterial pharyngitis, although cefuroxime axetil (250 mg twice a day for 10 days) is even more effective for primary treatment and can be effective for persistent infection.[A4] In patients with proven recurrent infections, clindamycin (300 mg orally four times a day for 10 days) or amoxicillin–clavulanic acid (875 mg orally twice a day or 500 mg three times a day for 10 days) is recommended. For patients who are allergic to penicillin, azithromycin (500 mg/day for 3 days) is another alternative. Evidence also suggests that a single dose of oral or intramuscular corticosteroids given at the start of treatment will reduce the pain of severe pharyngitis, especially in children.[A5] In patients with recurrent symptomatic episodes despite appropriate antimicrobial therapy, tonsillectomy can decrease future throat infections, at least in the short term, compared with continued observation.[A6]

Non–group A β-hemolytic streptococcal infections (Chapter 269), including groups B, C, and G, can cause acute pharyngitis with a clinical picture that mirrors that of group A β-hemolytic streptococcal pharyngitis. Glomerulonephritis is a known sequela, whereas rheumatic fever is not. Penicillin or clindamycin, as prescribed for group A β-hemolytic streptococcus, provides adequate coverage.

NONSTREPTOCOCCAL BACTERIAL PHARYNGITIS

A variety of bacteria other than streptococci can infect the throat. For example, *Fusobacterium necrophorum*–positive pharyngitis, which clinically resembles

ABSTRACT

Nearly every systemic and infectious disease results in head and neck manifestations, with the majority affecting the upper aerodigestive tract. Diseases of the upper aerodigestive system include infection (acute and chronic; viral, bacterial, and fungal), systemic disease, and neoplasm, some of which require urgent care or referral to an otolaryngologist. Abnormalities of swallowing, respiratory function, voice, and speech are influenced by the anatomic site involved, the host's immune status and inflammatory response, the severity of the disease process, and the presence or absence of neurologic involvement. In a patient with hoarseness, current clinical practice guidelines recommend visualization of the larynx for symptoms that persist for 3 months or longer; however, warning signs of a potentially serious or emergent throat condition warrant referral regardless of duration. These conditions include persistent throat pain with or without trismus, difficulty in swallowing, difficulty in breathing, hemoptysis, and ear pain with normal findings on the ear examination. Diagnostic testing options, which include rigid and flexible fiberoptic laryngoscopy, imaging, pulmonary function studies, and laboratory testing, are directed by history, symptoms, and physical findings. This chapter introduces non-otolaryngologists to head and neck disorders that would likely present to a general practice. Emphasis is placed on diagnosis, testing, initial treatment, and criteria for referral to a specialist.

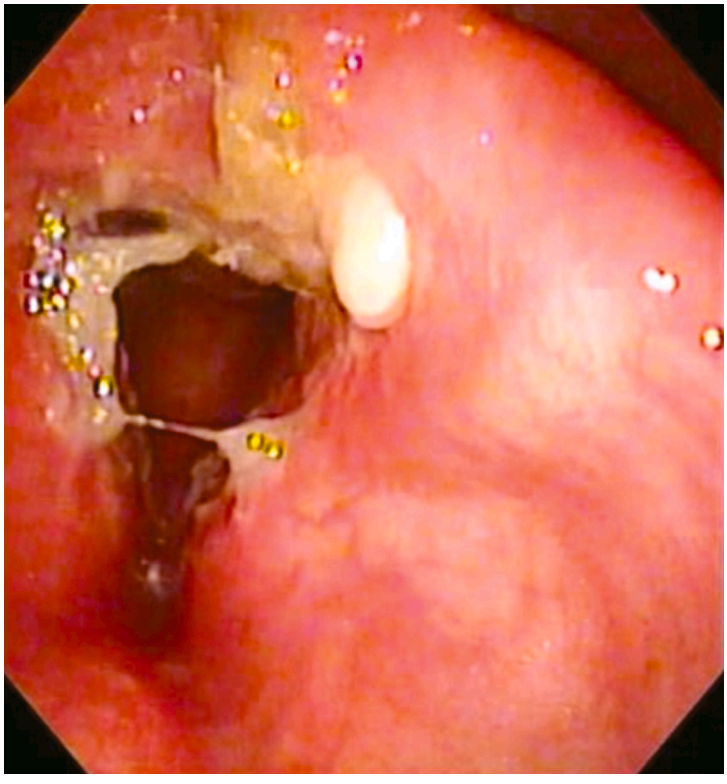

FIGURE 397-2. Fiberoptic laryngoscopy demonstrating chronic laryngitis secondary to methicillin-sensitive *Staphylococcus aureus* infection. Diagnosis is based on culture and biopsy.

streptococcal pharyngitis, occurs more frequently than group A β-hemolytic streptococcus–positive pharyngitis in a student population.[5] *Staphylococcus aureus* (Chapter 267) infections, whether caused by methicillin-resistant (MRSA) or methicillin-sensitive (MSSA) strains, usually are manifested with chronic hoarseness. About 30% of patients with bacterial laryngitis will have MRSA infection.[6] Laryngoscopy typically reveals thickened erythematous vocal folds with edema, whitish debris, and crusting, which may resemble leukoplakia (Fig. 397-2). Trimethoprim-sulfamethoxazole (160 mg/800 mg twice daily for 2 to 4 weeks) is generally effective, but treatment should be guided by antibiotic sensitivities.

Bordetella pertussis (Chapter 289) infections have become more common in adults because of their gradual loss of immune protection after vaccination. Adults typically present with cough, often but not always accompanied by nonspecific upper respiratory symptoms, fever, and leukocytosis. A *B. pertussis* serum immunoglobulin G titer higher than 27 IU/mL is highly predictive of recent infection. Erythromycin (500 mg four times a day for 14 days) or azithromycin (500 mg single dose orally on day 1, then 250 mg daily on days 2 through 5) is effective treatment.

Neisseria gonorrhoeae (Chapter 275) can cause sexually transmitted gingivitis, stomatitis, glossitis, and pharyngitis, especially in men who have sex with men. Treatment is the same as for urogenital disease and should include treatment for chlamydia. Options include ceftriaxone, 500 mg intramuscularly in a single dose, and doxycycline, 100 mg orally twice daily for 7 days. *Treponema pallidum* (Chapter 295) can cause oral and oropharyngeal ulcerations that involve the lips, tongue, and tonsil. Treatment is the same as that recommended for systemic disease. *Chlamydia* (Chapter 294), which is commonly associated with pneumonia and bronchitis, also can cause pharyngitis and hoarseness, sometimes as its presenting symptoms. *Mycoplasma pneumoniae* (Chapter 293), which frequently accounts for 15 to 20% of cases of community-acquired pneumonias, also can cause sore throat, nasal congestion, and coryza. Treatment of chlamydia and mycoplasma infections with tetracyclines, macrolides, and quinolones is the same as for the pneumonias they cause (Chapters 293 and 294).

Francisella tularensis (Chapter 287) is a gram-negative bacillus that causes tularemia. Oropharyngeal involvement is associated with fever, pharyngeal erythema, exudative tonsillitis, and tender lymphadenopathy. A false-positive monospot test result and atypical lymphocytosis can mimic infectious mononucleosis. The organism is sensitive to macrolides, fluoroquinolones, and tetracyclines.

Corynebacterium diphtheriae infection (Chapter 272) involves the mucosal surfaces of the upper respiratory tract, where it causes a patchy gray-black pseudomembrane in the nasopharynx, oropharynx, larynx, and trachea. About 75% of patients complain of throat pain. Airway obstruction and severe dysphagia are life-threatening sequelae. Antitoxin is given in combination with penicillin, erythromycin, tetracycline, clindamycin, or rifampin.

Arcanobacterium haemolyticum (Chapter 272) is a gram-positive bacillus that can cause pneumonia, meningitis, osteomyelitis, brain abscess, and peritonsillar abscess in both normal and immunocompromised patients. Uncomplicated pharyngitis may be treated with erythromycin (250 mg four times a day). Complicated infections require intravenous dosing with vancomycin, clindamycin, or cephalexin, with or without gentamicin (see Table 266-4 in Chapter 266).

PERITONSILLAR ABSCESS AND DEEP SPACE INFECTIONS

Only about 1% of patients with acute bacterial pharyngitis develop serious suppurative complications.[7] The best predictors are severe tonsillar inflammation and severe earache, but most complications occur in patients with neither of these findings. Peritonsillar abscesses usually can be diagnosed on physical examination (Fig. 397-3) and managed by an otolaryngologist in an outpatient setting by surgical drainage, needle drainage, or medical therapy. In uncomplicated patients without trismus, medical therapy appears to be equally safe and efficacious.[A7] Patients treated with medical therapy

FIGURE 397-3. Left peritonsillar abscess identified by bulging anterior pillar and soft palate with midline shift. (Courtesy Thomas A. Tami, MD.)

FIGURE 397-4. Mononucleosis with symmetrical exudative tonsillitis. (Courtesy Thomas A. Tami, MD.)

also experience less pain, use fewer opioids, and miss fewer days of work.[8] Oral antibiotics, such as clindamycin (300 to 450 mg four times a day for 14 days) or amoxicillin-clavulanate (875 mg orally twice a day for 10 days), are recommended. The addition of metronidazole does not add benefit in otherwise healthy adults who are treated with incision and drainage, and it can increase adverse events.

By comparison, patients with deep neck abscesses often have swelling of the external neck, trismus, torticollis, and even a compromised airway due to infection that has spread to the fascial planes of the neck and chest. These infections require urgent evaluation, usually with a computed tomography scan with contrast enhancement. Aggressive management includes incision and drainage as well as broad-spectrum intravenous antibiotics that cover aerobic and anaerobic bacteria (ampicillin-sulbactam, 3 g every 6 hours; ceftriaxone 2 g intravenously every 24 hours; levofloxacin 750 mg intravenously every 24 hours plus metronidazole 500 mg every 6 hours; or clindamycin 600 mg intravenously every 8 hours).

Severe infections of the pharynx can cause septic thrombophlebitis of the internal jugular vein (Lemierre syndrome), an uncommon but serious complication. Patients typically present with persistent fever, difficulty in swallowing, neck pain, and a neck mass due to an underlying peritonsillar, retropharyngeal, or parapharyngeal abscess. Diagnosis is best established with a contrast-enhanced computed tomography scan of the neck. This potentially life-threatening condition is almost always associated with anaerobic infection, especially with *F. necrophorum* or *A. haemolyticum* (Chapter 273). Infection can extend into the intrathoracic vasculature, and patients can develop bacteremia and septic pulmonary emboli. Treatment should be directed toward anaerobic coverage (empiric coverage with piperacillin-tazobactam 3.375 g intravenously every 6 hours, a carbapenem such as imipenem 500 mg intravenously every 6 hours, meropenem 1 g intravenously every 8 hours, ertapenem 1 g intravenously every 24 hours, or ceftriaxone 2 g intravenously every 24 hours plus metronidazole 500 mg intravenously every 8 hours). Anticoagulation with heparin is controversial and generally reserved for persistent septic emboli. Surgical intervention includes drainage of the abscess. Ligation or excision of the jugular vein may be indicated for persistent septic emboli unresponsive to medical management. Mortality rates can be as high as 5%.

VIRAL INFECTIONS

Prior to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic (Chapter 336), the common cold (Chapter 329) caused 30 to 60% of cases of pharyngitis, with rhinovirus (Chapter 329) accounting for the majority of cases, followed by coronavirus (Chapter 334) and parainfluenza (Chapter 331) (see Table 397-2). U.S. adults experienced an average of 2.5 episodes per year of noninfluenza, non-coronavirus disease 2019 (COVID-19) upper respiratory infections, each with a 7.4-day average duration of symptoms. These 500 million episodes historically cost an estimated $40 billion annually, in part because of associated systemic symptoms such as fever, cough, and sinusitis and in part because of associated exacerbations of allergies, asthma, and chronic obstructive pulmonary disease. With COVID-19, the incidence of essentially every other viral pharyngeal infection declined markedly because of masking and social distancing, but their rates undoubtedly will increase back toward or to historic levels as such restrictions are lifted.

The viral infection that is most likely to be confused with a bacterial infection is mononucleosis. Mononucleosis is caused by Epstein-Barr virus (Chapter 348), which has a seroprevalence of 67% in U.S. children and adolescents aged 6 to 19 years. After an incubation period of 3 to 7 weeks, patients present with initial malaise, fever, and chills followed by sore throat, fever, and anorexia.[9] Some patients have associated abdominal discomfort due to splenomegaly or hepatomegaly, headache, stiff neck, and rash. On physical examination, patients have erythematous pharyngitis with exudative tonsillar hypertrophy (Fig. 397-4), prominent lingual tonsils, and adenoid hypertrophy (Waldeyer ring). Aphthous-type ulcerations and petechiae may be seen, especially at the junction of the hard and soft palate. Impressive cervical adenopathy is typical, and 50% of patients have splenomegaly. Lymphoid hyperplasia can cause some degree of upper airway obstruction in about 5% of patients.

A blood count will show lymphocytosis, usually with more than 10% atypical lymphocytes. The heterophil antibody test result is often positive, and Epstein-Barr virus–specific antibody tests are diagnostic. β-Lactam antibiotics, which may mistakenly be prescribed, will cause a maculopapular rash in 95% of patients. Laryngeal obstruction may require hospitalization and intravenous corticosteroids (e.g., dexamethasone, 8 mg intravenously three times a day).

Influenza virus infection can include nonexudative pharyngitis, but the predominant symptoms are tracheobronchial, usually accompanied by fever, headache, rhinorrhea, cough, and myalgia, without lymphadenopathy. Adenovirus (Chapter 333) can cause pharyngitis associated with fever, nonproductive cough, nasal congestion, myalgia, headache, nausea, vomiting, and diarrhea, especially in outbreaks, such as among military recruits or in immunocompromised patients.

Primary herpes simplex virus (Chapter 345) infection is characterized by pharyngitis with or without gingival stomatitis. Symptoms include sore throat, fever, and malaise; physical findings include erythema and hypertrophy of the tonsils with exudates, often with enlarged, tender cervical nodes. It may be difficult to distinguish clinically from group A β-hemolytic streptococcal pharyngitis unless patients have herpes-like lesions of the oral cavity or oropharynx.

Human immunodeficiency virus infection (Chapter 353) can be manifested as an acute retroviral syndrome that mimics infectious mononucleosis and resolves in 1 to 2 weeks. The diagnosis must be considered in febrile patients with known risk factors. Once infection is established, oral and oropharyngeal infectious ulcerations may be due to herpes simplex virus, cytomegalovirus, syphilis, cryptococcus, histoplasmosis, or mycobacteria. Large, painful, noninfectious aphthous ulcers also can involve the tonsillar fossa, floor of mouth, hypopharynx, and epiglottis (Chapter 393). In adults with a sore throat that does not warrant antibiotics, a single 10-mg oral dose of dexamethasone does not improve symptoms at 24 hours but does modestly improve symptoms at 48 hours.[A8]

FUNGAL INFECTIONS

By far, the most common fungal infection of the oropharynx and larynx is candidiasis. *Candida* (Chapter 310) is a normal commensal organism of the oral cavity and oropharynx, but it can be an opportunistic infectious agent

FIGURE 397-5. **Fiberoptic laryngoscopy demonstrating characteristic erythema and white pseudomembrane secondary to *Candida* infection.**

in immunocompromised patients, patients who have received prior head and neck irradiation, patients with xerostomia or diabetes, and immunocompetent patients who have been treated with antibiotics or with systemic or inhaled steroids. *Candida* infection is manifested with sore throat, burning of the mouth and tongue, dysgeusia, dysphagia, and hoarseness. White pseudomembranes characteristic of thrush (Fig. 397-5) may involve the oral cavity, oropharynx, hypopharynx, larynx, and esophagus. Treatment includes oral hygiene, probiotics, and topical antifungals (Chapter 310). Fluconazole (200 mg orally on the first day followed by 100 or 200 mg once a day for 14 to 21 days) is indicated for laryngeal and esophageal involvement and for recurrent disease. In patients who do not respond to fluconazole, resistant *Candida albicans* and non-*albicans Candida* species are likely causes and should be treated with itraconazole (200 mg orally once a day for 14 to 21 days).[10]

Other fungal infections may affect the oropharynx and larynx in isolation or as part of a systemic infection. *Blastomycosis* (Chapter 308) involves the larynx in less than 5% of cases, in which it produces pseudoepitheliomatous hyperplasia and clinically resembles squamous cell carcinoma. *Histoplasmosis* (Chapter 308), which is endemic to the Ohio and Mississippi river valleys, can involve the oral cavity, oropharynx, and larynx in immunocompromised patients. *Cryptococcosis* (Chapter 309) can involve the larynx and occurs most often in an immunocompromised host, in whom pseudoepitheliomatous hyperplasia may occur.

Paracoccidioidomycosis (Chapter 308) is the leading cause of fungal laryngitis in South America, especially among farmers. It causes pseudoepitheliomatous hyperplasia that can be misdiagnosed initially as squamous cell carcinoma. *Coccidioidomycosis* (Chapter 308), which is endemic to the southwestern United States, can involve the larynx, in which it results in hoarseness and throat pain and can progress to airway obstruction. For each of these fungal diseases, treatment is similar to what is recommended for the disseminated disease (Chapter 307) that usually accompanies pharyngeal and laryngeal disease.

MYCOBACTERIAL INFECTIONS

The risk that tuberculosis (Chapter 299) infection will involve the oropharynx and larynx is low, with only about 1 to 1.5% of infected tuberculosis patients having involvement of the tonsils or larynx. Tonsillar involvement, which most often occurs in the presence of systemic disease, is manifested as sore throat with exudative tonsillitis and cervical adenopathy. Other diseases that can have a similar clinical presentation include lymphoma (Chapter 171), squamous cell carcinoma (Chapter 176), and sarcoidosis (Chapter 83). Tuberculosis in the larynx is most likely to involve the vocal folds and supraglottis (false vocal folds). It is manifested with hoarseness and odynophagia, and its lesions mimic squamous cell carcinoma. Approximately 50% of cases occur in the presence of active disseminated disease, about one third occur with inactive disease, and the other 15% occur as primary laryngeal disease.

In contrast, *Mycobacterium leprae* infection (Chapter 301) is manifested with laryngeal disease in one third of patients with systemic disease. The clinical picture is indistinguishable from that of laryngeal tuberculosis. Atypical mycobacteria rarely involve the larynx, and infection most often is manifested as cervical adenopathy.

CHRONIC TONSILLITIS

Patients may develop deep tonsillar crypts that accumulate debris, such as food or sloughed mucosa, thereby providing an ideal environment for the growth of bacteria, especially anaerobes. Such patients commonly complain of whitish or yellow pieces of semisolid debris on or emanating from their tonsils. These tonsilliths often have a foul taste and odor, and they can cause halitosis. Some patients have chronic sore throats because of the persistent infection. Treatment includes frequent gargling of a hydrogen peroxide mouthwash and occasionally expressing this debris from the tonsil manually. Long-term amoxicillin (500 mg three times a day for 21 days) or clindamycin (300 mg orally three times a day for 21 days) may be effective; however, the presence of *Actinomyces*, a commensal organism of the oral cavity and oropharynx, is indicative of chronic infection that requires tonsillectomy because even long-term antibiotics are unlikely to be effective. Multiple episodes of acute tonsillitis, especially if accompanied by a peritonsillar abscess, can also be an indication for surgery. Adenotonsillectomy decreases the number of episodes of sore throat and days with sore throat in children in the first year after surgery, but its value in adults is less clear. Many adults improve spontaneously, and the potential benefit of surgery must be weighed against its risks,[11] including hemorrhage and pain, the latter of which is more prevalent in adults.

EPIGLOTTITIS

Epiglottitis (supraglottitis) is an uncommon problem in adults and has become even less common in children because of routine *Haemophilus influenzae* vaccination in children (Chapters 15 and 277). In adults, *Streptococcus pneumoniae* (Chapter 268) is now the most common organism, and adults present with a severe sore throat, odynophagia, fever, and "hot potato" voice. Airway obstruction occurs less frequently than in children, although it should be considered a possibility.[12] Palpation or movement of the larynx causes significant pain. On transnasal fiberoptic laryngoscopy, the larynx typically reveals swelling, erythema, and occasionally exudates of the epiglottis and other supraglottic structures. Patients with a confirmed diagnosis of epiglottitis require intravenous antibiotics (e.g., cefotaxime, 2 g every 6 hours, or ceftriaxone, 1 to 2 g/day, intravenously), and they should be observed in an intensive care unit setting until symptoms improve because of the risk for rapidly progressive airway obstruction.

NONINFECTIOUS PHARYNGITIS

LARYNGOPHARYNGEAL REFLUX

Patients with gastroesophageal reflux disease (Chapter 124) can develop laryngopharyngeal reflux with intermittent hoarseness, nighttime or chronic cough, postnasal drip, "globus" sensation, reactive airway disease, halitosis, and brackish or acid taste in the back of the mouth and throat. Findings on laryngoscopy, although nonspecific, may include posterior laryngitis, with swollen and erythematous arytenoid cartilages, thickening of the vocal folds, interarytenoid edema, and thickening of the mucosa. In severe cases, spasm or thickening of the cricopharyngeus muscle, also known as the upper esophageal sphincter (Chapter 124), can cause dysphagia as a result of poor pharyngeal emptying or even spillage of secretions into the larynx with aspiration.

Treatment should address dietary change, behavioral modification, elevation of the head of the bed at night, and a therapeutic trial of a proton pump inhibitor for up to 3 months (Chapter 124).[13] Empirical treatment without laryngoscopy is reasonable in patients with classic symptoms, but patients who do not respond within 3 months or patients with warning signs (e.g., ear pain, trismus, or odynophagia) require laryngoscopy to exclude more serious causes of hoarseness. In patients with persistent symptoms and a positive pH probe or with evidence of Barrett esophagitis, an antireflux procedure (Chapter 124) should be strongly considered.

SYSTEMIC DISEASES OF THE THROAT AND LARYNGITIS

About 80% of patients with *pemphigus* (Chapter 406) will have symptoms affecting the nasal cavity, oral cavity, and oropharynx, and half of these patients will have laryngeal involvement. Shallow ulcerations with fibrinous material and surrounding erythema are characteristic. Bullous lesions are less likely to be observed because the epithelial layer sloughs during swallowing. Laryngeal involvement may result in stenosis with airway obstruction due to scarring. Upper aerodigestive tract involvement occurs in 35% of patients with *pemphigoid* (Chapter 406), and 50% of these patients will have laryngeal involvement. Treatment in both disorders consists of high-dose steroids (prednisone, 75 to

100 mg orally per day until remission) during the attack phase and then tapered to a maintenance dose. Other immunosuppressive medications, such as azathioprine, cyclophosphamide, or cyclosporine (Chapter 28), may be required in the maintenance phase. Perilesional or intralesional triamcinolone acetonide injections are recommended during the maintenance phase for new lesions.

Granulomatosis with polyangiitis (Chapter 249) includes laryngeal involvement in 20% of patients, with a predilection for the subglottis (E-Fig. 397-1). Presenting symptoms may include hoarseness, cough, dyspnea, wheezing, and stridor. Flow-volume loops are useful and demonstrate flattening of both inspiratory and expiratory loops characteristic of a fixed extrathoracic obstruction. Patients presenting with airway obstruction require surgical intervention. Active disease with granulation tissue requiring airway management is treated with endoscopic dilation and steroid injection. Systemic immunosuppression is not effective for treatment of laryngeal involvement, so open resection may be required as the disease becomes chronic with the deposition of fibrous tissue.

Relapsing polychondritis involves cartilage in the ear, nose, and upper and lower airway as well as in the articular joints and costal cartilage. About 50% of patients will develop dyspnea, cough, hoarseness, stridor, or wheezing due to the destruction of cartilage and the resulting loss of structural support of the airway (E-Fig. 397-2). Airway obstruction may necessitate stenting or tracheostomy.

About 25 to 30% of patients with rheumatoid arthritis (Chapter 243) develop hoarseness, globus symptoms, and difficulty in swallowing. Hoarseness may result from acute inflammation or chronic nodular formation. Bilateral arytenoid joint involvement may impair vocal fold motion and cause airway obstruction with stridor. Surgical intervention may be necessary to open the airway. The role of steroids (systemic or injectable) for airway stenosis in rheumatoid arthritis has not been established.

About 1 to 5% of all patients with *sarcoidosis* (Chapter 83) develop laryngeal involvement, usually manifested as hoarseness. As the disease progresses, however, it can cause a conical stenosis due to thickening of the soft tissue (E-Fig. 397-3). Laryngeal paralysis can be caused by a mass effect or by adenopathy with peripheral nerve compression along the course of the vagus or recurrent laryngeal nerve. Vocal fold involvement responds to intralesional steroid injection, but endoscopic laser excision is recommended in patients with airway symptoms.

Amyloid (Chapter 174) can deposit anywhere in the upper aerodigestive tract. In patients with localized immunoglobulin light chain amyloidosis, the most common site is the larynx (about 14% of cases). Hoarseness and cough are the most common symptoms in patients with laryngeal involvement (E-Fig. 397-4), but pharyngeal involvement may be associated with pain. Airway obstruction is rare. Surgical debulking with or without external beam radiation may relieve symptoms and even resolve the lesions. Unfortunately, reports are anecdotal, and there are no large series to support treatment options.

NEUROLOGIC DISORDERS AFFECTING THE THROAT

Neurologic disorders of the oropharynx, hypopharynx, and larynx may be due to focal diseases or be a local manifestation of generalized neurologic disease. Head and neck manifestations of neurologic and neuromuscular disorders are classified as hyperfunctional and hypofunctional disorders. Hyperfunctional disorders include muscle tension dysphonia, dystonia (Chapter 379), essential tremor (Chapter 379), myoclonus, and stuttering. Hypofunctional neurologic disorders include Parkinson disease (Chapter 378), multiple sclerosis (Chapter 380), neuromuscular disorders (Chapters 387 and 390), postpolio syndrome (Chapter 349), myopathies (Chapter 389), medullary disorders, and laryngeal paralysis. Given the variety of disorders with head and neck manifestations, it is critical to identify and classify the physical findings and associated symptoms. For example, a patient who complains about the sound of the voice may in fact have a normal voice but actually have severe dysarthria and hypernasality secondary to amyotrophic lateral sclerosis. The site of the lesion associated with the neurologic disorder will result in characteristic physical findings and facilitate establishment of a correct diagnosis (Table 397-3).

Hyperfunctional Neurologic Disorders

In *dystonia* (Chapter 379), spasmodic dysphonia fluctuates moment to moment and day to day. Adductor spasms of the vocal folds produce strained, strangled vocal quality with pitch breaks. Abductor spasms produce breathy hypophonic word breaks. Nonspeech sounds (laughter) and singing voice may be normal. This condition responds well to botulinum toxin injections.

Muscle tension dysphonia, which may be difficult to distinguish from dystonia, can occur secondary to underlying weakness (paresis, aging) with compensatory hyperfunction. Speech has a rough strained quality, perhaps with pitch breaks, and does not fluctuate moment to moment. It generally responds to voice therapy.

Vocal tremor is seen in 30% of patients with *essential tremor* (Chapter 379) and may be associated with spastic dystonia. Patients have a tremulous, quavering vocal quality, with or without head or hand tremor. Because of involvement of pharyngeal and laryngeal muscles, botulinum toxin may not be effective.

Myoclonus (Chapter 379) causes rhythmic contraction of the palate, pharynx, or larynx at a rate of one or two per second. Patients may have audible clicking from the eustachian tube or larynx. Voice may or may not be affected. Palate and vocal folds may be treated with botulinum toxin.

Pseudobulbar palsy (Chapters 373 and 387) causes spasticity and hyperreflexia of the bulbar muscles (pharynx, palate, lips tongue, and larynx). Patients develop dysarthria, hypernasality, and a harsh, strident, strained vocal quality, which is more spastic than spasmodic.

TABLE 397-3 CORRELATING SITE OF LESION WITH PHYSICAL FINDINGS IN NEUROLOGIC DISORDERS AFFECTING THE THROAT

SITE OF LESION	SIGNS
Cortex	Aphasia Aphonia Dysarthria Dysphonia Stridor
Extrapyramidal system	Vocal strain and pitch breaks Tremor Hypophonia/tachyphemia Spasmodic movements Focal, regional, or generalized dystonia
Cerebellum	Ataxia Dysmetria Tremor Incoordination
Brain stem	Flaccid paralysis Associated dense sensory deficit
Peripheral	Focal paresis or paralysis Other cranial nerve ± Palate involvement defines location

Modified from Blitzer A, Alexander RE, Grant NN. Neurologic disorders of the larynx. In: Flint PW, Haughey BH, Lund VJ, et al., eds. *Cummings: Otolaryngology–Head and Neck Surgery*. 6th ed. Philadelphia: Mosby Elsevier; 2015.

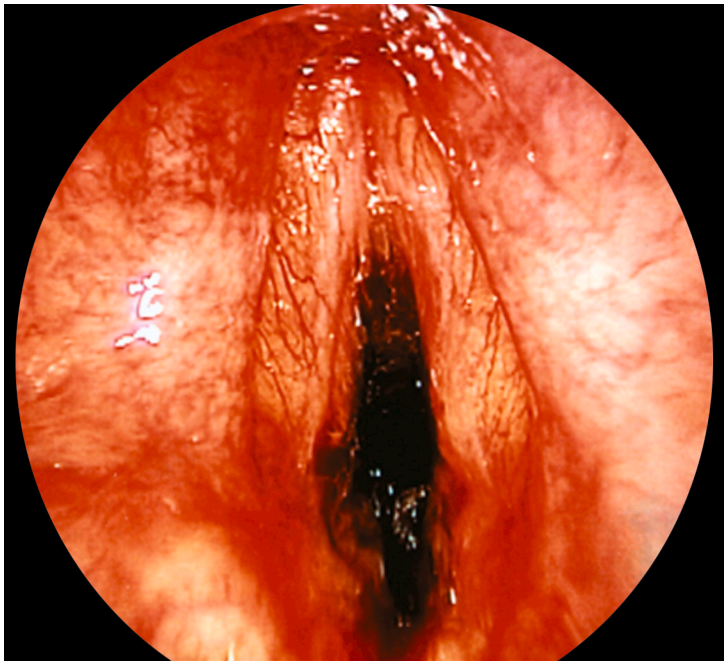
Hypofunctional Neurologic Disorders

Parkinson disease affects speech and swallowing in more than 80% of patients. Patients have dysarthria, prosody of speech, hypophonia, tachyphemia, monotonous pitch, and absence of vocal tremor.

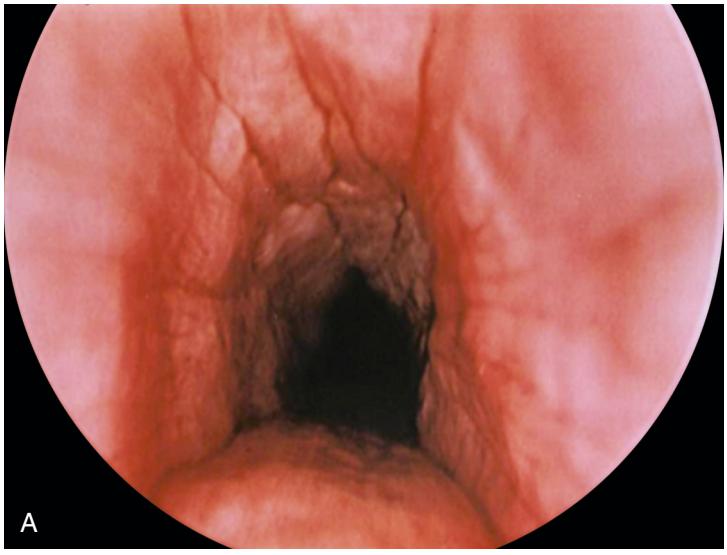
Laryngeal examination shows bilateral vocal fold bowing with incomplete glottic closure. In advanced disease, vocal fold motion becomes hypokinetic. Pooling of secretions occurs as swallowing dysfunction progresses. Patients benefit from early intervention by speech-language therapists to address both voice and swallowing symptoms. In *progressive supranuclear palsy*, bulbar symptoms progress more rapidly, with pronounced speech and swallowing difficulty (Chapter 378). In *multiple system atrophy* (Chapter 378), progressive airway obstruction from bilateral vocal fold motion impairment may necessitate tracheostomy. In *myasthenia gravis* (Chapter 390), hypernasal speech, palatal weakness, and hypophonia may be accompanied by difficulties with swallowing and respiration. Some patients with *amyotrophic lateral sclerosis* (Chapter 387) present with bulbar symptoms that result from buccal-labial-lingual weakness, which produces speech and swallowing dysfunction, before the definitive diagnosis is made. In *multiple sclerosis* (Chapter 380), dysphonia and dysarthria are common.

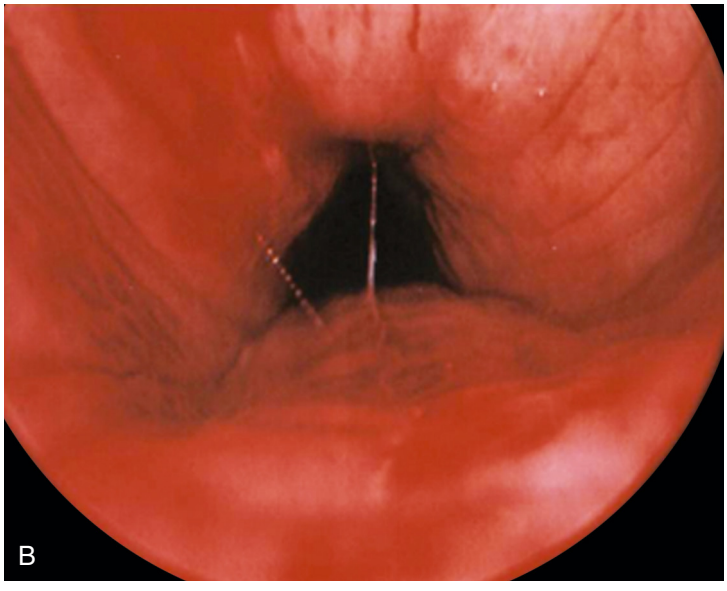
LUMP IN THE THROAT

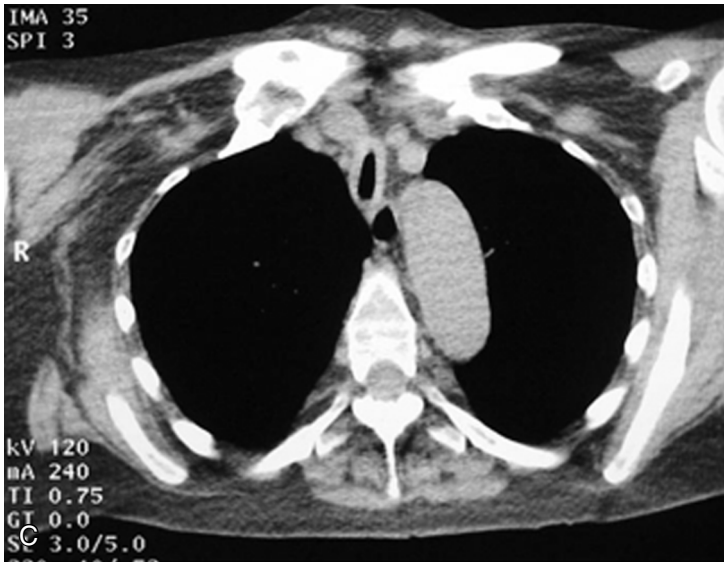
The sensation of a lump in the throat, called *globus pharyngeus*,[14] should prompt a careful history and physical examination by an otolaryngologist to exclude a serious diagnosis. When no underlying anatomic disease is found, possible causes include gastroesophageal reflux and spasm of the cricopharyngeus. Cognitive-behavioral therapy may be helpful.



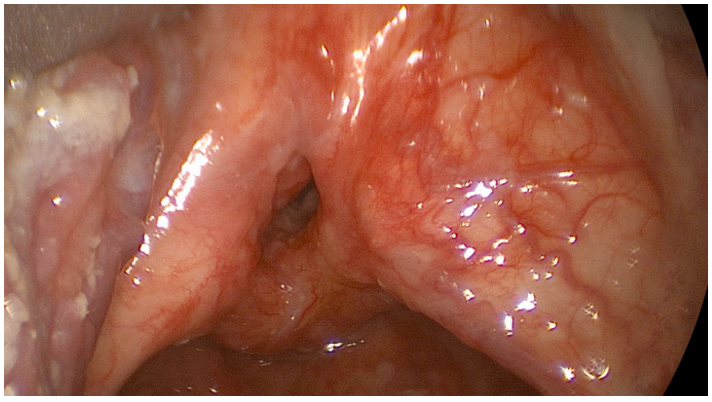
E-FIGURE 397-1. Fiberoptic examination of a patient with granulomatosis with angiitis demonstrating laryngeal involvement at the level of the vocal folds and subglottis.



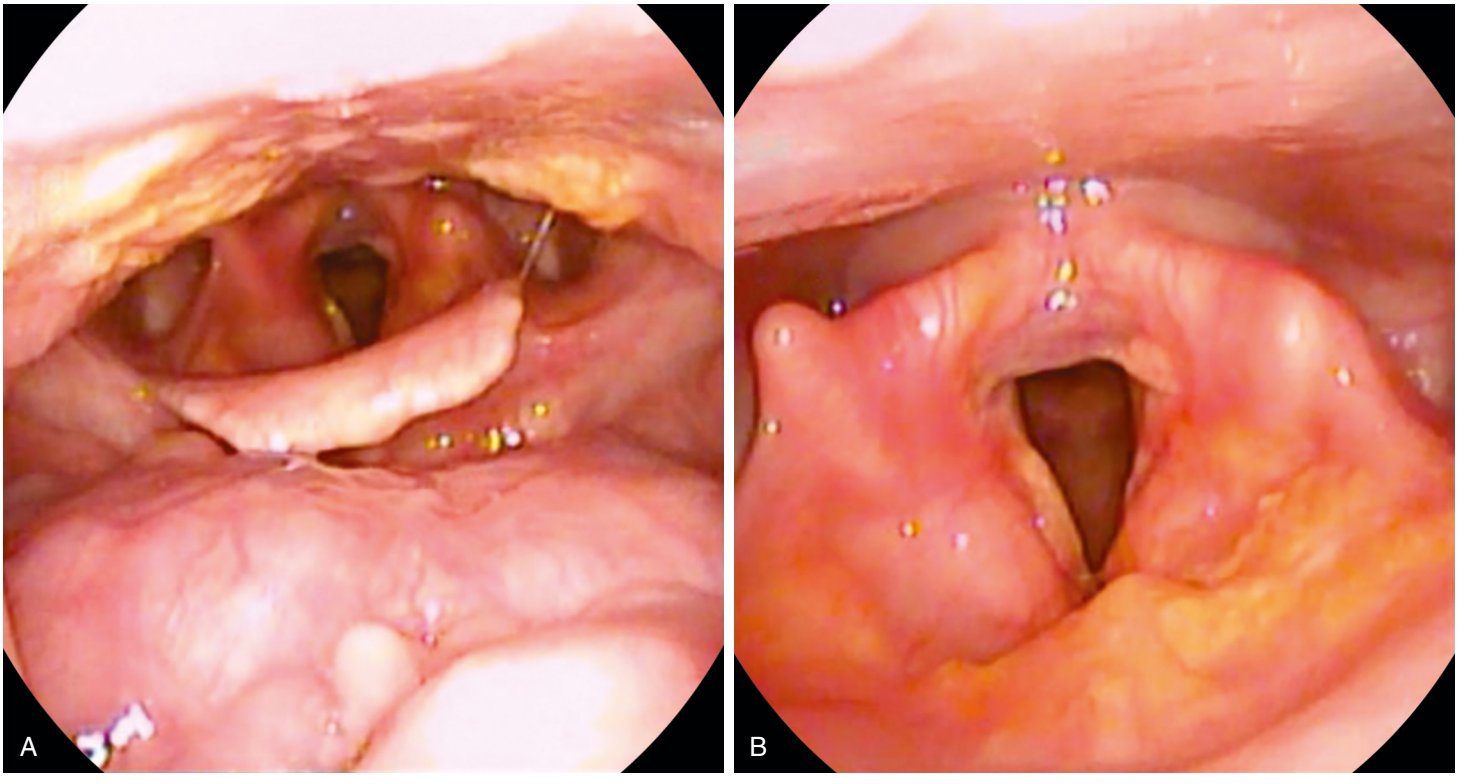




E-FIGURE 397-2. Tracheoscopy in a patient with relapsing polychondritis with tracheal involvement. **A**, On inspiration, negative intrathoracic pressure maintains a patent airway. **B**, During expiration, positive intrathoracic pressure collapses the airway because of loss of tracheal ring support. **C**, Computed tomography scan demonstrating thickening of the tracheal wall.



E-FIGURE 397-3. Supraglottic stenosis secondary to sarcoid demonstrating granulomatous destruction of epiglottis and aryepiglottic folds.



E-FIGURE 397-4. Amyloid deposition in the hypopharynx (A) and supraglottis and glottis (B).

HOARSENESS

Hoarseness, also called dysphonia, is characterized by altered voice quality, pitch, loudness, or vocal effort. Relevant history includes smoking status, occupation, and recent procedures involving the neck or affecting the recurrent laryngeal nerve. Symptomatic treatment should be considered in patients who have evidence suggesting a recent bacterial infectious process or gastroesophageal reflux without any historical features, such as ear pain, dysphagia, or odynophagia, or physical findings such as adenopathy or oral lesions suggestive of tumor. Additionally, there is no evidence to support the use of antibiotics or oral corticosteroids in patients with hoarseness unless otherwise indicated for a specific cause. Hoarseness that does not resolve within 4 weeks, or a history or physical examination suggesting a serious cause, should prompt referral to an otolaryngologist for laryngoscopy.

The symptom of hoarseness invariably points to the larynx as the site of disease. Benign lesions are most common, including vocal nodules (screamer's nodules), vocal cord cysts, vocal cord granulomas (usually resulting from intubation trauma or laryngeal hyperfunction), and vocal cord papillomas. Malignant neoplasms must be suspected (Chapter 176), especially in patients with a strong smoking history.[15]

Of the malignant tumors that can occur in the hypopharynx and larynx, squamous cell carcinoma is the most common and is usually associated with tobacco and ethanol use. However, the incidence of human papillomavirus–related oropharyngeal squamous cell carcinoma is increasing and should be considered in the nonsmoking population. Squamous cell carcinoma (Chapter 176) can occur on essentially any mucosal surface in the head and neck. Symptoms can range from mild sore throat to hoarseness, severe dysphagia, and odynophagia. Pain is often referred to the jaw or ear. Associated cervical lymph node enlargement is also common in advanced disease. Successful management depends on early detection by a careful examination of the entire upper aerodigestive tract, biopsy with histopathologic examination, and aggressive treatment based on the clinical stage and site of the lesion.

LARYNGEAL PARALYSIS

Laryngeal paralysis most often is manifested as a unilateral paralysis as a result of a mediastinal tumor; surgical trauma during thyroid, carotid, or anterior cervical spine surgery; blunt or penetrating trauma; aortic aneurysm; progressive neurologic disease; or viral or idiopathic causes. The severity of impairment can be determined from subjective criteria based on the patient's symptoms, such as breathiness, aspiration, and exertional intolerance.

Unilateral vocal fold paralysis with a favorable prognosis occurs after blunt trauma, endotracheal intubation, idiopathic vocal fold paralysis, and paralysis associated with viral pathogens (Ramsay Hunt syndrome). In this setting, the severity of aspiration, dysphonia, and electromyographic findings can be used to determine the choice of procedure and timing of intervention. Temporary medialization with collagen injection is warranted in patients with unilateral paralysis and a good prognosis. Patients who have poor prognosis for recovery include those with injury after complete section of the nerve during a surgical resection of tumor, invasion of cranial nerves by a tumor, paralysis associated with thoracic aneurysm, or paralysis due to progressive neurologic disorders. In patients with a low likelihood of recovery, permanent medialization of the paralyzed vocal fold is warranted.

Bilateral vocal fold motion impairment, which is less common, has the same causes. Its management is most often directed toward improving the airway because the predominant symptom is airway obstruction.

Laryngeal and Subglottic Stenosis

Airway injury may result in both glottic and subglottic stenosis. The most common causes of glottic stenosis are iatrogenic bilateral recurrent laryngeal nerve injury and intubation injury, which result in bilateral impairment of laryngeal motion. The most common causes of subglottic stenosis include prolonged intubation and tracheostomy. Early tracheostomy can reduce laryngeal trauma and the incidence of both laryngeal and subglottic stenosis.[16] With the acute respiratory compromise associated with COVID-19 infection (Chapter 336), the initial approach of delaying tracheostomy[17] was associated with airway injury and airway obstruction,[18] thereby reinforcing the adverse consequences of delaying tracheostomy, especially in patients who receive mechanical ventilation in the prone position.[19] However, changes in voice, most frequently caused by unilateral vocal fold paralysis, and swallowing issues were not reduced by earlier tracheostomy. Fortunately, however, most patients have improved speech and swallowing within the first week, especially with speech and swallowing therapy.

398 PRINCIPLES OF MEDICAL CONSULTATION

GERALD W. SMETANA AND BARBARA A. SLAWSKI

APPROACH TO MEDICAL CONSULTATION

A general medical or subspecialty physician may receive a request to perform a consultation for a variety of purposes. In some settings, a single consultative encounter will be requested, or the consultant will determine that only one visit, either in the inpatient or in the outpatient setting, is necessary. More commonly, the approach will include one or more follow-up visits to meet the goals of the requesting physician, patient, and consultant. The consultant generally assumes one of four roles: (1) cognitive consultant, (2) procedural consultant, (3) comanager with shared care, or (4) comanager with principal care. The consultant as a comanager continues to care for a component of the patient's needs in an ongoing fashion while being careful to coordinate this comanagement with the requesting physician. Finally, in some situations, it may be most appropriate that the physician who initially requested the consultation no longer play an active role in the care of the patient but rather transfer ongoing care exclusively to the consultant. An example would be a referral to an oncologist for a new diagnosis of cancer that will require intensive chemotherapy and periodic restaging.

From a practical perspective, consulting physicians enter into the consultative mode in a relatively limited number of ways.[1] Surgeons may request a preoperative medical consultation to assess operative risk and obtain recommendations regarding perioperative care (Chapter 399) or, after surgery, to seek help in managing specific postoperative complications or assisting in the patient's long-term management. Both general medical physicians and medical subspecialists appropriately seek help from a subspecialist with particular knowledge in problems outside their own area of expertise to reduce uncertainty. Sometimes these requests are for specific medical procedures, but requests often seek cognitive guidance as well. Finally, noninternists may seek medical consultation for reasons other than perioperative care. For example, a psychiatrist may request a consultation to help determine whether the somatic symptoms of a particular patient represent important medical conditions (Chapter 402). In the peripartum setting, specific complications of pregnancy may require sophisticated medical consultation (Chapter 221).

Each of these settings raises different challenges for the medical consultant. In all settings, however, a number of general principles apply and can improve the effectiveness of consultations. In this chapter, we discuss these principles. Above, all, communication between physicians and other team members is critical to the process of consultation in all settings. The burgeoning patient safety movement has developed best practices for "hand-offs" that can be applied to consultations.

CONSULTATIVE SETTINGS

Consultations occur in both the outpatient and inpatient environment. In the inpatient environment, medical consultations are commonly performed by hospitalists in both the academic and community settings. Most hospitalists are trained in internal medicine or family medicine, but hospitalists specializing in fields such as neurology and obstetrics are becoming more common. The hospitalist may act as the primary physician who is seeking a consultation, as a consultant for medical or nonmedical physicians, or enter into a comanagement relationship with a nonhospitalist physician.

SETTING-SPECIFIC CONSULTATIVE ISSUES

An effective consultant must recognize the setting in which the consultation is requested and possess the required content knowledge. Distressingly, a number of studies have demonstrated that the requesting physician and the consultant often have substantially different views on the reasons that a consultation was requested. This initial disconnection, if present, will substantially decrease the efficacy of any medical consultation.

PREOPERATIVE SURGICAL CONSULTATION

In the preoperative setting, the medical consultant should not "clear" a patient for surgery and must avoid the temptation to do so even if asked. Clearance may incorrectly imply that the procedure or patient has no risk for adverse outcomes in the perioperative period. Instead, the medical consultant should help determine the inherent risk of the proposed procedure for the particular patient, whether the patient is in the best possible condition for surgery, and whether any generic or patient-specific interventions would reduce this risk (Chapter 399). Effective consultation also requires a specialized knowledge base, whether the consultation is focusing on a particular organ system or on overall perioperative risk (Chapter 399). The most important attributes of a preoperative medical consultation are a careful history and physical examination and an understanding of key literature and recommendations guiding perioperative care. Diagnostic testing plays a secondary role in this setting and may result in surgical delays, cancellations, or adverse patient outcomes if inappropriately ordered. The consultant can help avoid unnecessary and repetitive preoperative testing that is costly in the aggregate with essentially no benefit.[2]

POSTOPERATIVE SURGICAL CONSULTATION

Surgeons often request a postoperative medical consultation when a complication has developed that is beyond their area of expertise (Chapter 401). These problems are commonly urgent, so the goal is expeditious consultation and prompt intervention. Management of these problems does not usually differ from management of the same problem in nonoperative settings, but specific surgery-related risks must be considered. For example, the management of anticoagulation in the perioperative setting may vary from the nonoperative setting. As surgical patients become older with more comorbid conditions, surgeons increasingly request postoperative comanagement to help reduce the risk of complications. Consultants should aid in the transition to the outpatient or long-term care setting as appropriate.

MEDICAL-MEDICAL CONSULTATIONS

Cross-consultations between medical subspecialists or between a subspecialist and a generalist, in either direction, are quintessential examples of collaboration.[3] For all consultations, the key is to provide the requested expertise and benefit without overstepping into the domain of the expertise of the requesting physician.

Shared care, which is defined as truly joint participation of primary care physicians and specialist physicians in the delivery of care for patients with chronic conditions, can improve outcomes for hypertension, depression, and other medical conditions.[A1] For example, a randomized trial of shared care for patients with hypertension and chronic kidney disease demonstrated lower blood pressures and better use of lipid-lowering drugs in the shared care group. Rapid infectious disease consultations may result in improved outcomes, including shorter length of stay, fewer readmissions, and less inappropriate use of antibiotics.[4] For example, mandatory infectious disease consultation has been associated with a lower 30-day mortality and improved quality of care in patients with *Staphylococcus aureus* bacteremia.[5]

A common example of medical-medical consultation is the situation in which a hospitalist assumes principal responsibility for an inpatient admission and then returns the patient to the primary care physician after discharge from the hospital. In this consultative interaction, close communication is critical because primary responsibility for the patient's care has shifted from the outpatient medical physician to the inpatient physician. This transfer of responsibility is not dissimilar to that occurring when a patient is submitted to the care of a subspecialist for a procedure such as cardiac catheterization or gastrointestinal endoscopy. Similar issues also arise when a critically ill patient with a condition such as a complicated myocardial infarction (Chapter 58) or shock (Chapters 92, 93, and 94) is managed principally by a critical care medical specialist and is then expected to return to the care of the primary physician after hospital discharge. However, a key difference is that the inpatient hospitalist physician, unlike the consulting subspecialist, will not typically have an ongoing comanagement role. Because of the risk for discontinuity, effective communication at the time of hospitalization, whenever key issues arise during hospitalization, and at the time of discharge is even more important in the inpatient hospitalist model than in the other settings in which subspecialists may take on more of a comanagement role. Effective and comprehensive hand-offs at the time of hospital discharge improve continuity and reduce the potential for errors and medicolegal liability.

CONSULTATIONS FOR SPECIAL POPULATIONS

When consulting for psychiatrists or in the peripartum period, the consultant requires special expertise to understand the different expressions of

ABSTRACT

Medical consultation is a common activity for both generalists and specialists. In this chapter, we discuss the approach to medical consultation, including specific consultative settings, preoperative medical consultations, comanagement, telehealth, and strategies for effective consultation.

To provide ongoing comanagement and become a partner in inpatient care • For an acute, unstable problem • For a chronic condition
To perform a procedure (or advise on whether to perform it) • Diagnostic • Therapeutic
To provide one-time or periodic advice • Diagnostic guidance • Therapeutic guidance • Reassurance • Medicolegal issues

TABLE 398-2 GUIDELINES TO HELP MAKE CONSULTATIONS EFFECTIVE

Determine whether the goal is to obtain advice (and, if so, specifically for what) or to aid in ongoing comanagement (see Table 398-1).
Understand the urgency of the consultation so that the consultation will be performed on a timely basis that meets the needs of the requesting physician and patient.
Perform a focused but careful history and physical examination—do not rely on information gathered by others.
Do not rehash information in an overly detailed note—emphasize the key issues your evaluation reinforced or discovered.
Be sure your recommendations are clearly listed and appropriately detailed—for example, indicate specific drugs, doses, and durations.
Limit the total number of recommendations to improve adherence.
Indicate how to monitor the effectiveness of your recommendations, as well as how to contact you urgently if problems arise.
Adjust your involvement (advice vs. comanagement) as appropriate, in concert with the requesting physician.
Serve as a peer—teach as appropriate but also seek to learn.
Remember that personal contact with the requesting physician, even if very brief, may be far more helpful than the best of written notes.
Do not disappear—follow the patient as frequently as appropriate, in coordination with the requesting physician.

For a more complete discussion of this topic, see Goldman L, Lee T, Rudd P. Ten commandments for effective consultations. *Arch Intern Med*. 1983;143:1753-1755; and Salerno SM, Hurst FP, Halvorson S, et al. Principles of effective consultation: an update for the 21st-century consultant. *Arch Intern Med*. 2007;167:271-275.

signs and symptoms in specific populations, as well as how and when to modify typical medical recommendations because of special circumstances (Chapters 221 and 402). Although these consultations occasionally result in long-term comanagement, more commonly they revolve around the resolution of an isolated problem or a perplexing condition.[6] In addition, the medical consultant should not make assumptions about the requesting physician's knowledge base regarding the specific medical issues that generate the consultation. The written report and verbal communications should be comprehensive and commonly include more basic medical content and specific recommendations than may be typical of a consultation for a medical subspecialist.

Subspecialty consultations requested by primary care physicians may be for advice, a technical procedure, or ongoing comanagement (Table 398-1). Consultations for general practitioners or family physicians generally follow the same guidelines as those for general internists. However, because both the training and ongoing practices of such physicians may or may not include the same spectrum and complexity of disease encountered by typical general internists, the subspecialty consultant must use judgment regarding both the initial consultation and the advisability of ongoing comanagement.

STRATEGIES FOR EFFECTIVE CONSULTATION

It is critical that requesting and consulting physicians agree about the reason for the consultative request. For example, the nature of a preoperative medical consultant's evaluation would differ substantially if the request were (1) routine, (2) for advice on perioperative insulin management in a patient with type 1 diabetes, or (3) to assist in determining the risks and benefits of proceeding to vascular surgery in a high-risk patient with coronary artery disease and a previous stroke. Effective communication at the time of the request will improve the value of the consultation and clarify the question. When there is doubt regarding the reason for the consultation, the consultant should speak directly to the referring physician before completing and documenting the evaluation of the patient.

Common reasons for medical consultation include assessment of perioperative risk; interpretation of a laboratory abnormality; help in performing a procedure, in obtaining advice, or in selecting therapy; and aid in providing long-term care. Prophylactic strategies (for example, venous thromboembolism, endocarditis, and surgical site infection) infrequently generate requests for medical consultation because they are commonly standardized to conform to practice guidelines at individual institutions.

Determining the question will also help narrow the scope of the consultant's advice and minimize the number of recommendations. Adherence by the requesting physician to any of the recommendations made by the consultant is higher for consultations with fewer recommendations. Another strategy to minimize the number of recommendations is to restrict advice to pertinent issues at the time, preferably in order of their importance.

Requesting physicians are also more likely to adhere to recommendations when the patient is sicker, the consultation is performed promptly, advice is given to institute specific therapy rather than perform more diagnostic testing, the consultant writes frequent follow-up notes, and computerized order entry support systems are used to convey recommendations. When giving advice about medications, consultants should indicate specific doses and duration of treatment. If a recommendation is likely to be controversial (e.g., postpone surgery), it is always preferable to speak directly to the requesting physician before writing a consultation note in the hope that direct conversation will provide an opportunity to develop a consensus that may then be reflected in the formal consultation note. In one study of 323 physicians, the three elements of greatest perceived importance for a high-quality consultation request were to frame the question, to indicate clearly whom to call with the response, and to establish urgency.

Consultants should be careful to restrict their advice to their particular area of expertise. For example, unless a particular antipsychotic medication is contraindicated because of a medical issue (Chapter 402), it is wisest to defer decision making regarding psychiatric management to the psychiatrist. A strongly worded consultation note that advises against a particular strategy will put another physician in a difficult medicolegal position if it differs from the physician's usual or recommended practice. The most important attributes of a consultative role are simple, concise recommendations and a clearly stated rationale for decision making. Detailed differential diagnosis is less important, and literature support is usually unnecessary.

Timely consultation reports improve physician satisfaction and patient care. For example, primary care physicians note that failure to receive timely reports from consultants limits their ability to provide high-quality care.

Salerno and colleagues have proposed modifications of Goldman's original "Ten Commandments" for effective consultations (Table 398-2). These recommendations serve as a helpful guide for consultants to improve adherence to their advice and, as a result, improve patient outcomes. Specific interactive training on the principles of consultation can increase the effectiveness of consultative communication.

SPECIAL CONSULTATIVE SITUATIONS

CURBSIDE CONSULTATION

Informal consultations are commonly called "curbside" consultations. In the current era, ready access to online medical references may potentially reduce curbside requests. Consultants in "cognitive" specialties such as infectious diseases, rheumatology, and endocrinology provide a disproportionate amount of informal (compared with formal) consultations. Informal consultations may occur by telephone, electronically, or in person. Curbside consultation is ingrained into the fabric of medical care.

Both generalists and specialists participate in an average of three to four curbside consultations per week. These consultations commonly involve questions about diagnostic tests, treatment plans, and the potential value of a formal consultation (which follows about one third of curbside consultations) in the future. To be effective, curbside consultations should be brief, involve a single question, and require no direct examination of the patient or medical records.

An important limitation of curbside consultations is that the consultant must rely on limited, secondhand information from the requesting physician rather than primary data from direct evaluation of the patient. Consultants report

that such indirect information is inaccurate in as many as half of curbside consultations. This reality, along with lack of financial compensation, leads to a greater degree of dissatisfaction with the curbside process by consultants than by requesting physicians. Salaried consultants may view a request for a curbside consultation more favorably than those whose livelihood depends on a fee-for-service model of care.

Although requesting physicians may perceive reduced medicolegal risk when they obtain and even document a curbside consultation, consultants may fear the risk for malpractice liability themselves when offering such advice. However, courts have consistently found that curbside consultants have no liability because no direct physician-patient relationship exists. Rather, the relationship is only between the requesting and consulting physicians.

ELECTRONIC CONSULTATIONS

Increasingly, physicians are using electronic communication, either as part of a shared electronic medical record or by e-mail, to supplement formal consultation requests.[7,8] An obvious advantage of this approach is that the requesting and consulting physician can communicate on their own schedules. Potential benefits include saving time, reducing costs, and improving continuity and access to specialty care. However, the lack of reimbursement for such activities may be a barrier to e-consultations.

MANDATORY CONSULTATIONS

In some situations, mandatory consultations may help enforce a standard of care. For example, mandatory inpatient infectious disease consultations, as part of an antimicrobial stewardship program, can improve the rational use of antimicrobial agents in the hospital and after discharge. Similarly, instituting routine consultation for patients with certain sentinel conditions, such as diabetes, may improve outcomes.

Telehealth Consultations

Historically, formal telehealth consultations were uncommon in large part because they were not a billable service. In 2020, driven by the coronavirus disease 2019 (COVID-19) pandemic, the Centers for Medicare & Medicaid Services relaxed previous constraints on billing for telehealth services as part of a declared public health emergency. As a result, telephone- and video-based telehealth services increased dramatically. Likely owing to convenience and safety, patients' satisfaction with telehealth services is surprisingly high despite the lack of an in-person physical examination.

This expansion has provided opportunities for creative and novel consultation strategies. Office-based specialists can provide telehealth consultations, even from a distance. Hospital medicine specialists also have used the expanded coverage of telehealth services in novel ways (Fig. 398-1),[9] including consultations at home, in post–acute care settings, and in emergency departments. Although the precise role of telehealth will likely evolve, especially if reimbursement regulations change, it can potentially change the landscape of medical visits (Fig. 398-2).[10]

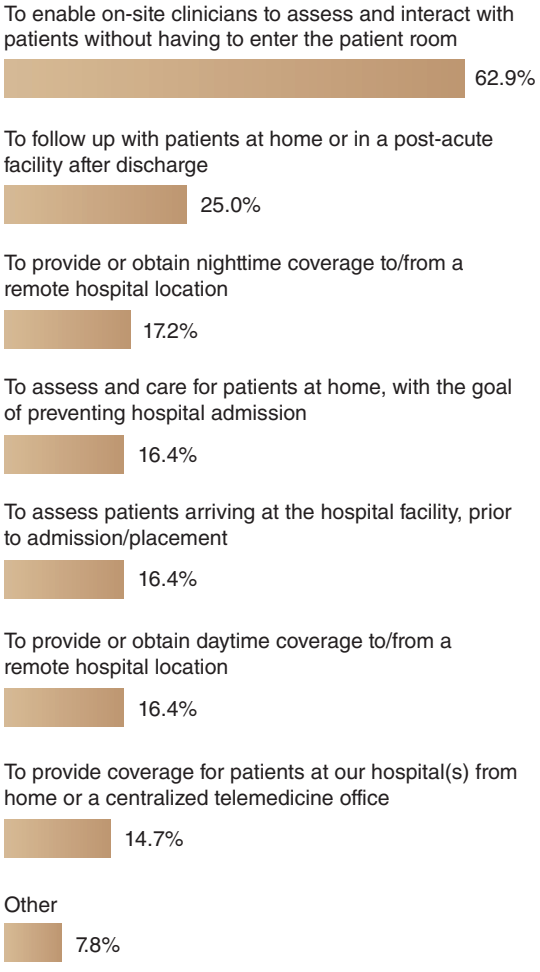

FIGURE 398-1. Use of telehealth technology among hospital medicine physicians. (From Society of Hospital Medicine. Hospital Medicine Groups Responding to the COVID-19 Pandemic: An Addendum to the 2020 State of Hospital Medicine report. https://www.hospitalmedicine.org/practice-management/shms-state-of-hospital-medicine. Accessed December 30, 2021.)

COMANAGEMENT

A consultation that begins with an initial encounter or a limited number of follow-up visits may evolve into ongoing comanagement. In such an arrangement, the physician initially serving in a consultative role becomes at least coequal to the requesting physician in the provision of ongoing care (see Table 398-1).

In some situations, the consultant may actually become the primary physician. This arrangement is obvious in situations in which the consultation was requested specifically for the provision of ongoing care. Other examples include situations in which an oncologist assumes principal care of a patient with a malignancy or a nephrologist assumes principal care of a patient with end-stage renal disease who is being maintained on dialysis. In some of these situations, a general internist who initially requested the consultation may now become the consultant and provide advice on preventive care and occasional help with intercurrent medical problems. This same transition in roles may occur temporarily in the inpatient setting when an outpatient primary care physician may retain a comanagement role even as a cardiologist cares for a patient with acute myocardial infarction, a pulmonologist cares for a patient in the ICU, a hospitalist cares for a patient in the general medical setting, or a noninternist addresses a specific problem.

More formal comanagement is now increasingly common in the hospital setting, where over 80% of hospitalists report that they comanage patients with specialists. Medical consultants may become comanagers of postoperative surgical patients, with a potential for improving outcomes. For example, hospitalist comanagement has been shown to improve quality and reduce costs for orthopedic, neurosurgical, and vascular surgery patients.[11,12]

In some institutions, comanagement for orthopedic or other surgical patients has become routine and does not require a specific request for consultation. In comanagement relationships, the comanaging specialist works as an active team member: writing orders; possibly rounding with the primary team; communicating with the staff, patient, and family; and participating in the coordination of care. Benefits of this model may include permitting the surgical team more uninterrupted time in the operating room, prevention and early diagnosis of medical complications, improved staff satisfaction, and improved outcomes. Because of the potential for gaps or duplication of care, comanagement relationships must develop and communicate specific interservice care agreements. These collaborative care agreements specify the care that will be delivered by each specialty to ensure optimal patient outcomes.

RESPONSIBILITIES OF THE CONSULTANT

The consultant is responsible to both the patient and the referring physician. A paternalistic approach is not desirable. The consultant should not limit communication to the referring physician and must not withhold discussion and recommendations from the patient. However, the consultant should not usurp the role of the referring physician, who remains responsible for assembling information and advice from varied sources, as well as for developing

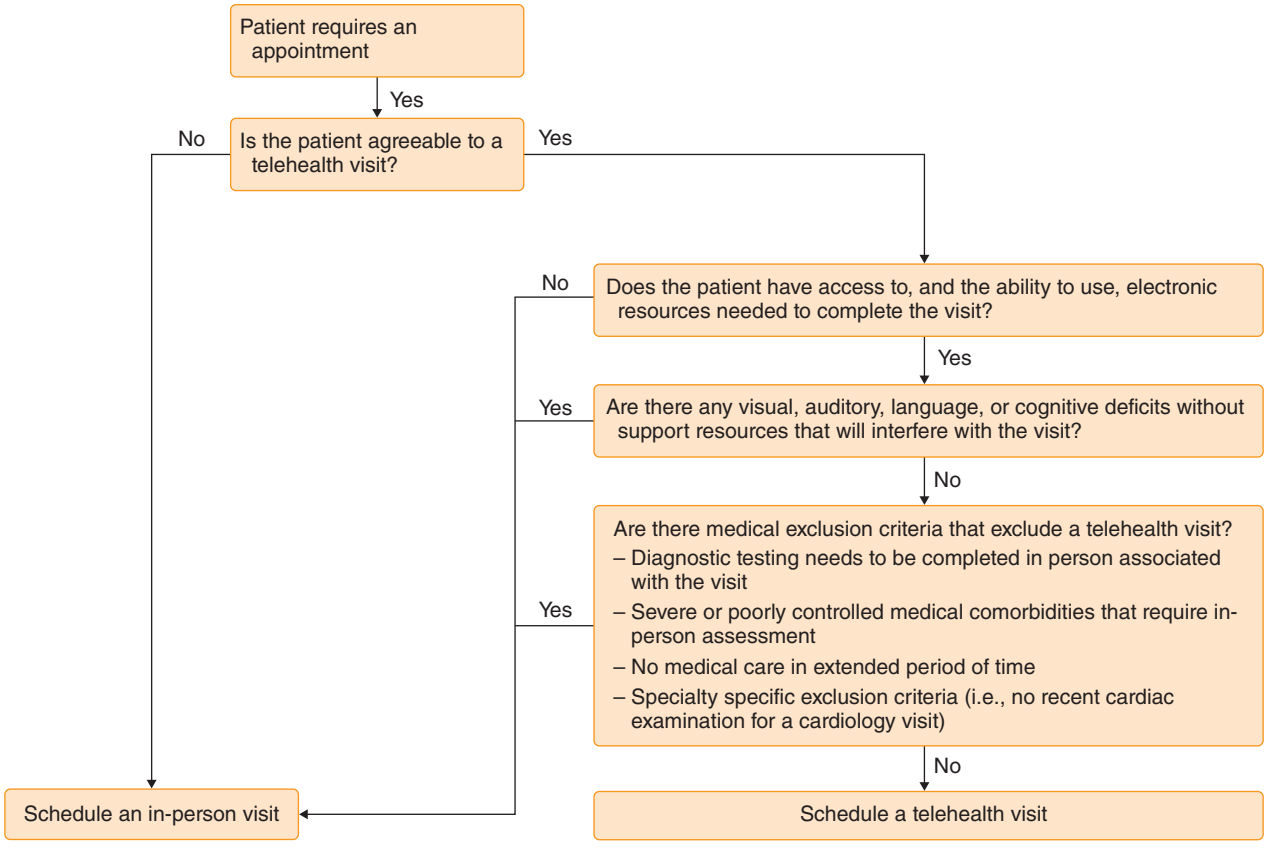

FIGURE 398-2. **Telehealth decision algorithm.**

an integrated plan with the patient. For example, in the preoperative setting, the consultant should not express a final opinion regarding the suitability of proceeding to surgery without first discussing all relevant considerations with the referring surgeon. Above all, the role of the consultant is to improve patient care and outcomes.

The consultant must execute his or her duty to the patient while acknowledging the collegial professional model of advising the primary physician. If, however, the patient's safety or welfare is at stake, the consultant's duty is foremost to be sure that the patient's needs always take precedence.

IMPACT OF CONSULTATIONS ON PATIENT OUTCOME

Few controlled trials have investigated the impact of medical consultations on outcomes. In one small study in the 1990s, an outpatient preoperative medical consultation reduced unnecessary admissions (those that did not result in surgery) compared with usual care (inpatient consultation at the discretion of the surgeon). In the outpatient setting, about 20% of diagnoses made by specialty consultants may be distinctly different than those made by referring physicians. Other reports indicate that anywhere from 5 to 50% of preoperative medical consultations result in changes in patient management. Comprehensive preoperative geriatric consultation can also reduce perioperative mortality among hip fracture patients.[A2]

399 PREOPERATIVE EVALUATION

ANDREW D. AUERBACH

Every year, more than 7 million patients undergo inpatient surgical procedures, and almost 10 million more undergo ambulatory surgeries. Although the incidence rate of adverse events, morbidity, and mortality have continued to fall as surgical, anesthetic, and medical management techniques have improved, an aging patient population with increasing medical complexity is undergoing a growing number of more ambitious and extensive surgical procedures.

Planning surgical and perioperative care generally begins with a preoperative evaluation by the surgical team (e.g., surgeon, anesthesiologist). Medical consultants are primarily responsible for evaluating of comorbid medical conditions and helping to maximize the safety of the perioperative course.[1]

GENERAL PRINCIPLES

The preoperative medical evaluation is a potential opportunity to diagnose and treat asymptomatic disease or to optimize medical management of chronic problems. Occasionally, such issues are urgent, should preempt the primacy of the surgical procedure, or are important for perioperative outcomes. Usually, however, these issues should be reserved for postoperative consideration by the patient and their outpatient physician rather than becoming a priority for a consultant who will not be directly involved in the patient's ongoing care. The preoperative medical consultant's evaluation and recommendations should avoid low-value or extraneous tests or treatments, while emphasizing a coordinated approach to improve the efficiency, quality, and value of care. In this model of care, the preoperative medical consultant is increasingly a member of a comanagement team,[2] with an active role in the direct ordering of diagnostic tests and therapeutic interventions.

399 PREOPERATIVE EVALUATION

ANDREW D. AUERBACH

Every year, more than 7 million patients undergo inpatient surgical procedures, and almost 10 million more undergo ambulatory surgeries. Although the incidence rate of adverse events, morbidity, and mortality have continued to fall as surgical, anesthetic, and medical management techniques have improved, an aging patient population with increasing medical complexity is undergoing a growing number of more ambitious and extensive surgical procedures.

Planning surgical and perioperative care generally begins with a preoperative evaluation by the surgical team (e.g., surgeon, anesthesiologist). Medical consultants are primarily responsible for evaluating of comorbid medical conditions and helping to maximize the safety of the perioperative course.[1]

GENERAL PRINCIPLES

The preoperative medical evaluation is a potential opportunity to diagnose and treat asymptomatic disease or to optimize medical management of chronic problems. Occasionally, such issues are urgent, should preempt the primacy of the surgical procedure, or are important for perioperative outcomes. Usually, however, these issues should be reserved for postoperative consideration by the patient and their outpatient physician rather than becoming a priority for a consultant who will not be directly involved in the patient's ongoing care. The preoperative medical consultant's evaluation and recommendations should avoid low-value or extraneous tests or treatments, while emphasizing a coordinated approach to improve the efficiency, quality, and value of care. In this model of care, the preoperative medical consultant is increasingly a member of a comanagement team,[2] with an active role in the direct ordering of diagnostic tests and therapeutic interventions.

ABSTRACT

In the past 10 years, the goals of preoperative evaluations have changed substantially. For elective and urgent procedures, the shift has been from focusing on identifying and "optimizing" medical conditions to identifying unstable medical problems, assessing functional status, and engaging a broad and interdisciplinary team so that perioperative care is coordinated safely and effectively. In situations in which surgery is needed to save a life or function emergently, preoperative evaluations are focused more narrowly on needs for postoperative management. Consultations should focus on gathering physical examination and historical data needed to use a validated risk calculator, with additional tests and procedures reserved for patients in whom these tests or procedures would be indicated regardless of the planned surgery. The incidence of major cardiac complications is relatively low and often secondary to other noncardiac complications. Common noncardiac complications include respiratory failure and pneumonia, delirium, venous thromboembolism, and hospital-acquired infections. Risks for these complications often also are linked to the risks for major cardiac outcomes (e.g., poor functional status, diabetes, baseline cognitive impairment), so preventive strategies recommended before surgery are likely to have broader benefit, particularly if coordinated with postoperative and posthospital care.

A clinical prediction rule for delirium after elective noncardiac surgery. *JAMA*. 1994;271:134-139.

The spectrum of complications of surgery (Table 399-1) includes relatively common life-threatening issues, such as postoperative myocardial infarctions, but also a range of morbid events, such as delirium or preventable medical complications (e.g., urinary tract infections). Postoperative complications usually are not solo events but instead frequently develop as part of cascades or clusters that represent the effects of several comorbid conditions and acute insults that may accrue during or even after hospitalization. Overlapping and cascading complications, often beginning with a low-mortality event, require the preoperative consultant to take a global view, often including multicomponent and interdisciplinary recommendations.

The consultant's role and recommendations should encompass a holistic and multicomponent approach to reducing risk by:

- Assessing the impact of the surgery in terms of its urgency and impact on prognosis.
- Assessing the patient's burden of illness, with a focus on understanding comorbid conditions, functional limitations, or medications that require close attention.
- Helping to identify new or unstable symptoms, and judiciously recommending or even ordering diagnostic tests and therapeutic interventions.
- Planning medical care, particularly ensuring standard preventive measures and coordination of medications, through the perioperative time period. Anticipate potential need for higher level of care, such as in an intensive care unit (ICU).[3]
- Relating recommendations, plans for postoperative follow-up (including expectations around comanagement), and anticipated discharge needs to the surgical team and patient.

PROGNOSTIC IMPACT AND TIMING OF SURGERY

The need for surgery (emergent, urgent, or elective) is largely determined by the surgeon, who chooses the operative approach and coordinates the anesthetic approach with the anesthesiologist (Chapter 400). Emergency surgery (which is needed immediately to save life or function) largely precludes lengthy preoperative evaluations. Urgent surgery sometimes provides limited time to gather information about preoperative risks, but the focus of the evaluation, as with emergency surgery, is on anticipating likely complications and planning postoperative care. In emergency and urgent surgery where medical prognosis is very limited (e.g., patient with advanced dementia) and the risks of surgery are high, the medical consultant should also focus on ensuring that the patient's and family's goals of care are aligned with the risks of surgery. For elective surgery, delay has less direct impact on prognosis, so time is available to conduct a more comprehensive preoperative evaluation (Fig. 399-1).

Although certain surgical approaches (e.g., open vs. laparoscopic vs. intravascular) are associated with variations in risks for medical complications, the primary driver of these choices is the surgeon. Similarly, specific anesthetics or anesthetic approaches (Chapter 400) may be associated with lower risk for certain complications (e.g., dexmedetomidine may be associated with lower risk for delirium, or neuroaxial anesthetic approaches may reduce risk for pulmonary complications), but the route of anesthesia has minimal effect on most postoperative outcomes, and the anesthesiologist is responsible for these choices. Nevertheless, the result of a medical preoperative evaluation can sometimes provide critical information needed to plan a surgical procedure.

GENERAL PREOPERATIVE EVALUATION

PREOPERATIVE HISTORY AND PHYSICAL EXAMINATION

The history and physical examination remain the mainstays of effective preoperative evaluations and provide global information about patient baseline burden of illness, risks, and prognosis. Although an understanding of the patient's baseline symptoms is important for a general picture of comorbidity and prognosis, the decision to pursue additional preoperative tests or treatments will largely be driven by whether the consultant uncovers new, unstable, or progressive symptoms or signs that would warrant evaluation even in the absence of a planned surgery.

History taking should focus on key comorbid conditions (e.g., diabetes or a history of coronary artery disease) that pose known risks for complications or require specific attention before, during, or after surgery, especially any medical problems that have required more intensive recent management. A full review of systems should include an assessment of chest discomfort, dyspnea, and functional capacity, as well as all comorbid symptoms and conditions. The family history should focus on bleeding abnormalities or a history of malignant hyperthermia.

Functional capacity should be assessed by determining the patient's ability to undertake specific activities (Table 14-1) that represent discrete levels of physical capacity based on the number of metabolic equivalents required to complete them. Patients who are able to sustain activities of 4 metabolic equivalents or greater (such as climbing a flight of stairs briskly without stopping, walking up a hill, or running a short distance) are generally considered lower risk, even with existing medical illnesses. By comparison, patients who are frail[4] and unable to perform such activities are at higher risk. In some cases, however, functional status is not easily obtainable because of orthopedic problems or pain; in such situations, clinical assessment of comorbid conditions and specialized risk indices may be especially helpful.

The past surgical history can provide important information about the patient's ability to withstand the stress of surgery as well as experiences with anesthesia, particularly bleeding or cognitive complications of surgery. Certain habits, such as smoking or alcohol use, can be helpful in planning treatments (e.g., nicotine replacement) and avoiding unexpected withdrawal symptoms after surgery.

A complete medication history is a key aspect of the preoperative evaluation because many consultants' recommendations will relate to the longitudinal management of medications during the perioperative period. Patients should be explicitly questioned about use of opioids, illicit substances, and herbal supplements. A complete recent medication history should be obtained, including over-the-counter medications. A careful bleeding history should be obtained. Allergies to any medication, foods, or latex should be determined. The physical examination should include basic physiologic measures, such as pulse, blood pressure, and weight. All patients should have a careful cardiac evaluation, including auscultation to detect any murmurs, and volume assessment. Baseline mental status, particularly chronic cognitive impairment or past episodes of delirium during acute illness, should be determined. A general survey appropriate to the patient's age and gender should follow, with subsequent focus on organ systems relevant to the patient's history or review of symptoms. For example, patients with a history of chronic obstructive pulmonary disease should have their oxygen saturation measured, lungs assessed for wheezing, and presence or absence of peripheral edema noted. Evaluation of the airway or dentition is generally performed by the anesthesiologist, but any abnormalities noted by the medical consultant should be

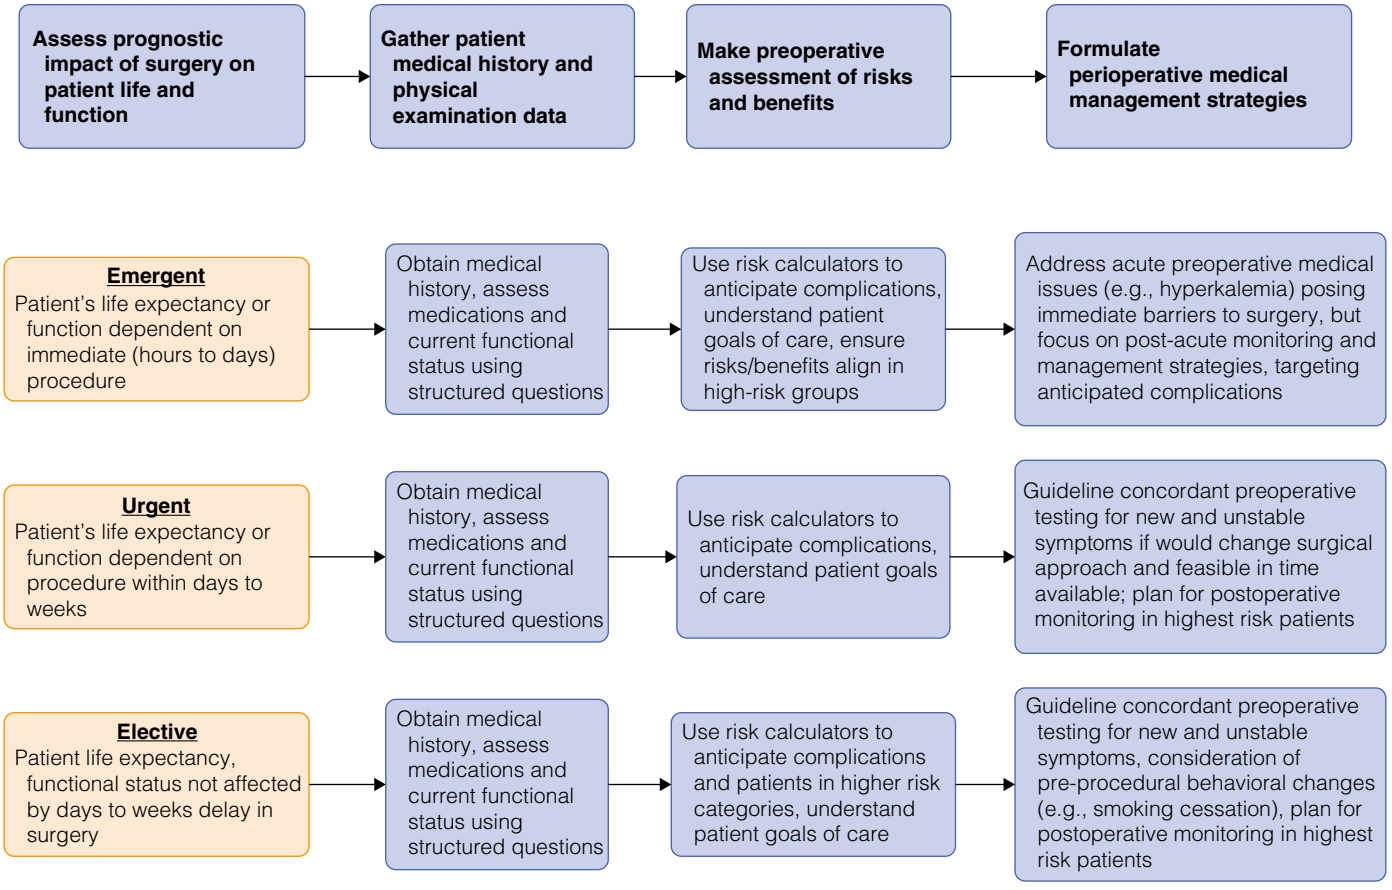

FIGURE 399-1. **Approach to preoperative evaluation according to surgical need.**

relayed. Point-of-care ultrasound, though potentially promising, is not part of a standard preoperative evaluation.

APPROACH TO PREOPERATIVE DIAGNOSTIC TESTING

Preoperative testing in asymptomatic patients rarely provides useful information, so most testing should be targeted based on the history or physical examination (Table 399-2), such as when a family history of bleeding prompts coagulation testing or a systolic murmur requires an echocardiogram to assess for possible aortic stenosis. In some situations, a preoperative test (e.g., an electrocardiogram in patients over age 40 years or with a history of cardiac disease and a chest radiograph for inpatients undergoing general anesthesia or with a history of lung disease) is also recommended as a baseline for comparison should postoperative problems (Chapter 401) occur. For patients with chronic illnesses or on chronic therapies that require monitoring (e.g., a creatinine level among patients with chronic kidney disease), a baseline perioperative value may prove useful.

ASSESSING RISK

In adult patients undergoing major inpatient noncardiac surgery, the combined risk of perioperative all-cause death, acute myocardial infarction, or acute ischemic stroke in the United States is about 3%. Overall surgical risk in an individual patient can be estimated using the American Society of Anesthesiologists' classification system. The risk of perioperative mortality is less than 0.03% in a normal healthy patient (class 1), but increases to 0.2% in patients with mild systemic disease (class 2), 1.2% in patients with severe systemic disease (class 3), 8% in patients who have severe systemic disease that is a constant threat to life (class 4), and 34% in a moribund patient who is not expected to survive for 24 hours without surgery (class 5). More detailed approaches can assess organ-specific risk, which is especially important in patients with underlying comorbid medical conditions.

CARDIOVASCULAR RISK

Risks vary by type of surgery (Table 399-3), with the highest risk for emergent operations and operations associated with prolonged anesthesia times, large fluid shifts, or bleeding. In these cases, risks are driven to a large degree by the underlying problem leading to the surgery, the circumstances of the surgery itself, and the patient's comorbid conditions. In high-risk surgeries, increased demand is placed on the cardiovascular system in the setting of a prothrombotic and inflammatory postoperative state, thereby leading to increased demand and subsequent ischemia, which in turn can lead to myocardial infarction (non-ST elevation or ST-elevation), arrhythmias, and sudden cardiac death.

The evaluation of a specific patient's risk for perioperative cardiovascular complications should focus on the patient's cardiovascular history, functional status, and cardiac physical examination.[5–7] Functional assessment should focus on the patient's metabolic equivalent (MET) level of activity, with the ability to perform 4 or more METs, suggesting that cardiac function can withstand the expected stress of surgery and, hence, is associated with a lower risk of perioperative cardiac complications. The presence of more than minimal aortic stenosis is not explicitly part of risk indices but should be specifically assessed on the cardiovascular evaluation.

Risk assessment prior to noncardiac surgery utilizes two separate strategies: assessing risk using a statistically validated risk index, and applying risk tools to consensus algorithms and guidelines. Two risk indices are widely used in clinical practice (Table 399-4). The Revised Cardiac Risk Index (RCRI) assigns single points for each risk factor category based on their importance as determined by prospective clinical evaluation and standardized follow-up. The National Surgical Quality Improvement Program (NSQIP) Myocardial Infarction and Cardiac Arrest index assigns points of varying weights for each individual factor identified by retrospective chart review. The Revised Cardiac Risk Index is potentially easier to remember and is not subject to biases in how patients may have been evaluated, whereas the Myocardial Infarction and Cardiac Arrest index uses web-based (https://riskcalculator.facs.org/RiskCalculator/) and spreadsheet-based tools. Either approach can guide additional risk stratification when the patient's estimated risk of cardiac events is greater than 1% (>1 Revised Cardiac Risk Index criteria).

Guidelines for applying these risk indices to patients who are scheduled to undergo elective or urgent noncardiac surgery begin with a clinical assessment for whether the patient is experiencing new or unstable symptoms that are indicative of an acute coronary syndrome (Fig. 399-2). This determination is followed by an estimation of cardiovascular risk combined with functional assessment to identify patients in whom additional testing is indicated.

TABLE 399-2 RECOMMENDATIONS FOR PREOPERATIVE LABORATORY TESTING

TEST	APPROXIMATE % ABNORMAL	APPROXIMATE % INFLUENCING MANAGEMENT	INDICATIONS
Hemoglobin	1.8	0.1	Expected major blood loss, symptoms of anemia, underlying cardiac or pulmonary disease, chronic kidney disease
White blood cell count	0.7	0.0	Suspected infection, myeloproliferative disorder, myelotoxic medications
Platelet count	0.9	0.02	Bleeding diathesis, myeloproliferative neoplasm, myelotoxic medications
Prothrombin time/INR	0.3	0.0	Bleeding diathesis, liver disease, malnutrition, antibiotic use, anticoagulants
Partial thromboplastin time	6.5	0.1	Bleeding diathesis, anticoagulant use
Electrolytes	13	1.8	Renal disease, medications affecting electrolytes (e.g., diuretics, digoxin, ACE inhibitor, ARBs)
Glucose	9	0.5	Known diabetes, taking glucocorticoids, morbid obesity
Renal function	8	2.6	Renal disease, diabetes, hypertension, major surgery, older age, medications affecting renal function
Liver function tests	0.4	0.1	Known liver disease, albumin level if at risk for needing postoperative parenteral nutrition
Urinalysis	19	1.4	No indication unless genitourinary symptoms or instrumentation planned (although often requested before joint replacement or spine surgery)
Electrocardiogram	25	2.6	Vascular surgery; intermediate-risk surgery with at least 1 RCRI risk factor; not indicated in asymptomatic patients undergoing low-risk procedures
Chest radiograph	20	3.0	Acute cardiopulmonary disease suspected based on history and physical examination, or surgery on heart or lungs

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; INR = international normalized ratio; RCRI = Revised Cardiac Risk Index (1 point each for coronary artery disease; heart failure; prior cerebrovascular accident or transient ischemic attack; diabetes mellitus on insulin; creatinine >2.0; and abdominal, thoracic, or suprainguinal vascular surgery) (see Table 399-4).

ASA = American Society of Anesthesiologists; ECG = electrocardiogram; NSQIP MICA = National Surgical Quality Improvement Program Myocardial Infarction and Cardiac Arrest index.

Preoperative stress testing is of low yield and generally not recommended unless patients meet guideline criteria for such testing (see Chapter 56) in the absence of a surgical procedure (as when a patient has new symptoms concerning for an acute coronary syndrome [Chapter 57]). In patients who have a greater than 1% estimated risk of a cardiovascular perioperative event, and who have poor functional capacity, additional risk stratification with noninvasive stress testing may be indicated if the patient is a candidate for revascularization and a delay in surgery is feasible. For such patients, pharmacologic (adenosine or dipyridamole) nuclear stress testing (Chapter 44) or dobutamine echocardiography (Chapter 43) are the recommended tests. The results of noninvasive stress tests correlate with cardiac risks of surgery but should be interpreted cautiously given that a strategy of preoperative coronary revascularization is not beneficial except in patients who have indications for percutaneous or surgical revascularization in the absence of the noncardiac surgery itself.

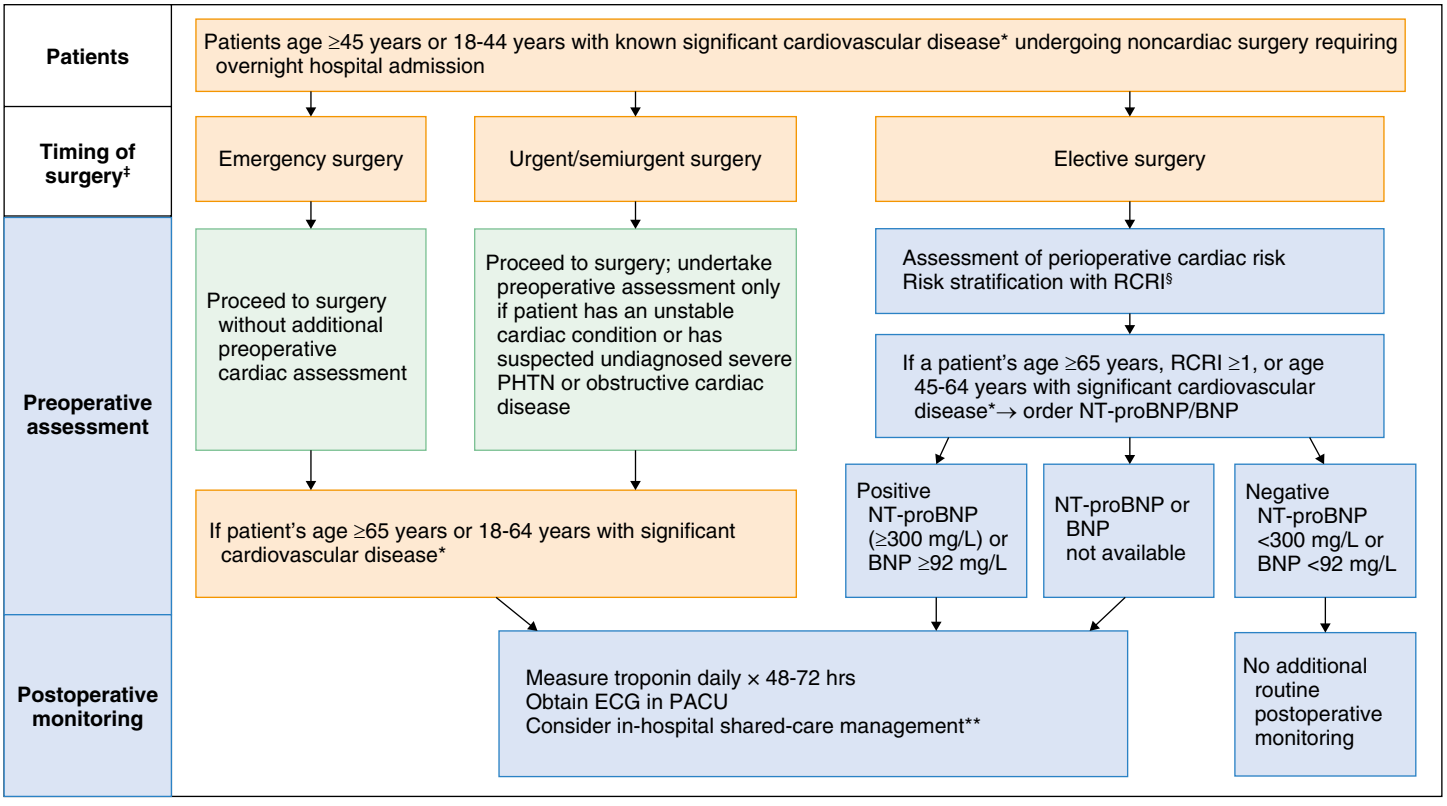
Preoperative biomarkers[8] (e.g., troponin levels, N-terminal pro-brain natriuretic peptide [NT-proBNP], and C-reactive protein) are included in some algorithms for preoperative evaluation (E-Fig. 399-1). Elevated NT-proBNP or BNP in patients with more than 1 Revised Cardiac Risk Index factor or known aortic stenosis may identify patients in whom more intensive postoperative monitoring is indicated. However, such an approach has not been prospectively validated, and it is not yet clear whether biomarkers can be used in a cost-effective manner to avoid unnecessary testing or postoperative monitoring.

TREATMENT

Risk Reduction Strategies

Medications

The routine use of perioperative β-blockers can reduce the risks of perioperative cardiac events (e.g., ischemia, atrial fibrillation, need for coronary interventions), but it increases overall mortality because of an excess of strokes and deaths



E-FIGURE 399-1. Canadian Association of Cardiology Algorithm. Preoperative risk assessment and postoperative monitoring flow diagram. *Significant cardiovascular disease includes known history of coronary artery disease, cerebral vascular disease, peripheral artery disease, heart failure, severe PHTN, or a severe obstructive intracardiac abnormality (e.g., severe aortic stenosis, severe mitral stenosis, or severe hypertrophic obstructive cardiomyopathy. †Timing of surgery refers to emergency surgery (e.g., severe trauma, ruptured aortic aneurysm), urgent surgery (e.g., hip fracture, bowel obstruction), semiurgent surgery (e.g., cancer with potential to metastasize), or elective surgery (e.g., knee arthroplasty). ‡If physical examination suggests there is an unknown severe obstructive intracardiac abnormality (e.g., severe aortic stenosis, severe mitral stenosis, or severe hypertrophic obstructive cardiomyopathy) or severe PHTN, then obtain an echocardiogram before surgery to inform the anesthesiologist, surgeon, and medical team of the type and degree of disease. If the history suggests the patient has an unstable cardiac condition (e.g., unstable angina), then discussion with the patient and surgical/medical team is required to decide whether to delay, cancel, or proceed with surgery. §RCRI score (each worth 1 point): history of coronary artery disease, cerebrovascular disease, congestive heart failure, preoperative insulin use, preoperative creatinine > 177 mmol/L, and high-risk surgery (i.e., intraperitoneal, intrathoracic, or suprainguinal vascular surgery). **Shared-care management refers to a multidisciplinary approach to inpatient postoperative care; this includes the surgeon and a medical specialist (e.g., internist, cardiologist, gerontologist), who will help with perioperative monitoring and management of cardiovascular complications. BNP = brain natriuretic peptide; ECG = electrocardiogram; NTproBNP = *N*-terminal pro-brain natriuretic peptide; PACU = post-anesthesia care unit; PHTN = pulmonary hypertension; RCRI = Revised Cardiac Risk Index. (From Duceppe E, Parlow J, MacDonald P, et al. Canadian Cardiovascular Society guidelines on perioperative cardiac risk assessment and management for patients who undergo noncardiac surgery. *Can J Cardiol*. 2017;33:17-32 and from Cohn SL. Preoperative evaluation. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.)

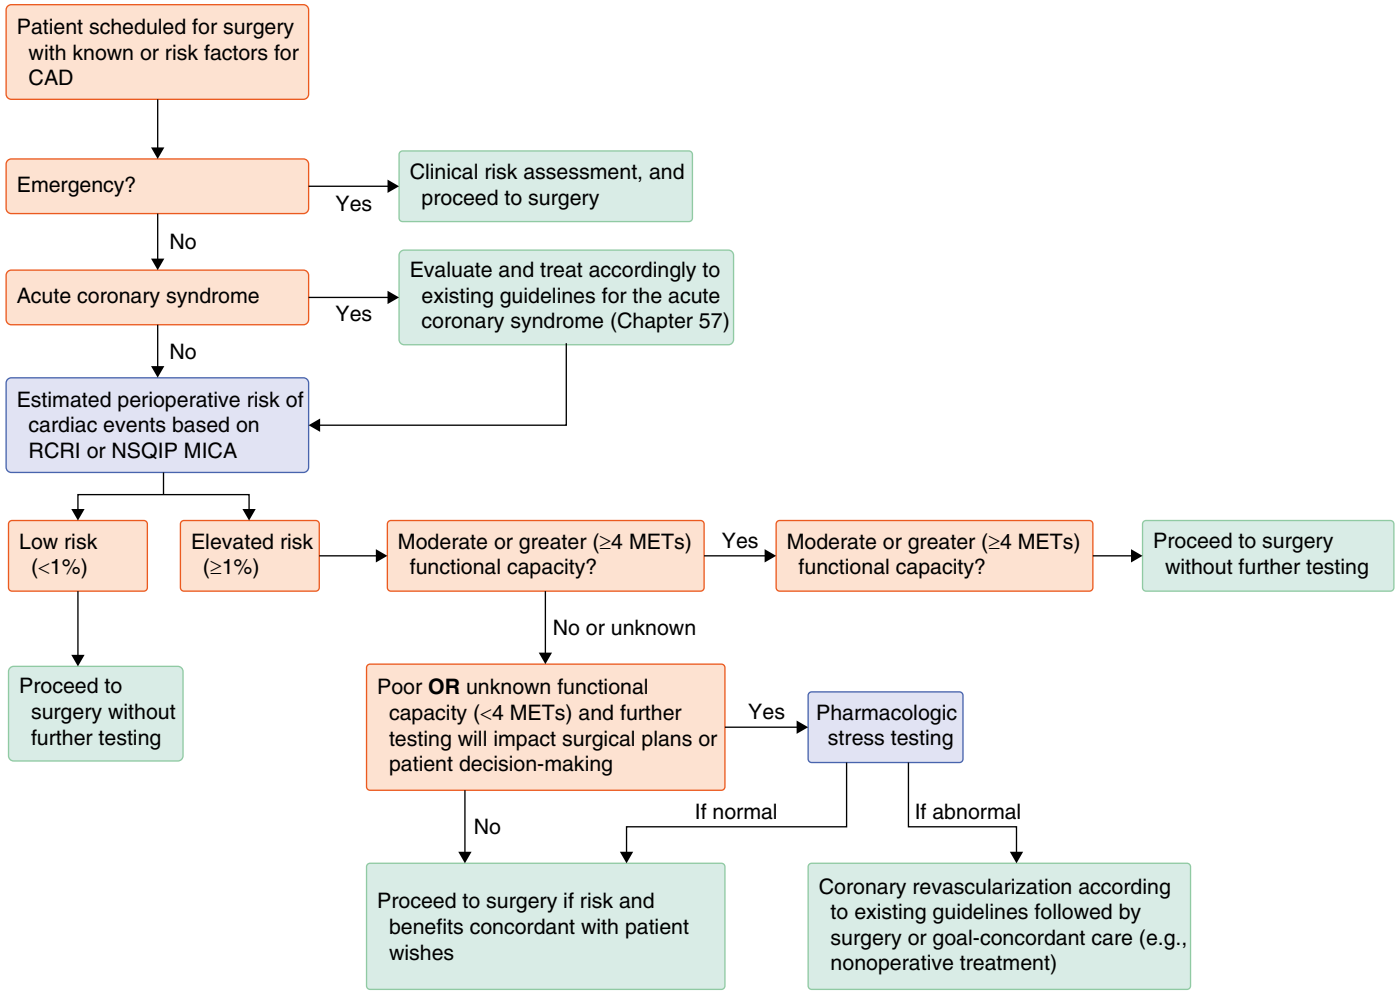


FIGURE 399-2. Approach to preoperative cardiac risk stratification. (Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:2215-2245.)

from noncardiac complications.[A1–A3] Clonidine, aspirin, or the combination of the two also do not confer benefit.

Current recommendations are to continue chronic β-blockers but not to start β-blockers except in patients in whom a long-term indication exists. The drug should be started early, at least 7 days before surgery, optimally within a time period that will allow assessment for clinical effectiveness and dose adjustment if appropriate. β-Blockers should not be begun on the day of surgery, particularly at high initial doses. In patients who have vascular disease and who are undergoing noncardiac surgery, statins may be associated with a lower risk for postoperative cardiovascular complications,[A4] but no data support starting them anew before surgery unless the patient has longer-term indications. Patients on statins should continue them through surgery.

Coronary Revascularization

High-quality evidence recommends against prophylactic revascularization, whether percutaneous or surgical, as part of perioperative risk reduction, unless the patient has an indication for revascularization independent of the planned procedures. If a patient meets criteria for intervention, the noncardiac surgery ideally should be delayed between 3 and 6 months, and sometimes as long as 12 months depending on the type of stent placed (Chapter 59) and the attendant need for dual-antiplatelet therapy. Noncardiac surgery can be performed within 2 weeks of balloon angioplasty, but it is a temporizing approach that anticipates a later and more definitive coronary stent.

Postoperative Monitoring

Postoperative monitoring, in the form of continuous cardiac monitoring, periodic electrocardiograms (ECGs), or measurement of troponin-I levels, is usually recommended only in patients who have symptoms (e.g., dyspnea, chest pain) or signs (e.g., tachycardia) that provide a potential indication of myocardial injury. However, some guidelines suggest obtaining a one-time ECG when higher-risk patients (e.g., RCRI >1) are in the post-anesthesia care unit, with subsequent cardiac monitoring if abnormalities are noted.

Monitoring of troponin-I levels after surgery (Chapter 401) has prognostic importance as an indicator of myocardial injury. Elevations in troponin are associated with higher risk of cardiac events or death following surgery. Common protocols measure troponin I within 6 hours of surgery and then daily for up to 3 days afterward in high-risk patients. Although troponin elevations portend a worse prognosis, no intervention is of proven value in otherwise asymptomatic patients. However, optimization of medications, particularly statins, aspirin, and diabetes medications—according to guidelines for secondary prevention of myocardial infarction (Chapter 58), is a reasonable approach.

OTHER CARDIAC RISKS

Heart Failure

Heart failure (Chapter 46) and is associated with a higher risk for postoperative cardiac events.[9] Although no data from randomized trials are available, it seems reasonable to be sure heart failure is optimally controlled preoperatively, and perhaps guided by preoperative NT-pro-BNP or BNP levels. Patients' volume status and symptoms then should be monitored carefully after surgery.

Valvular Heart Disease

Aortic and mitral valvular diseases (Chapter 60) are associated with higher risks of postoperative cardiac events, but optimal approaches in patients who are otherwise asymptomatic and stable are undefined. Evidence suggests that careful attention to blood pressure and volume management during and after surgery may improve outcomes.[10] Transcatheter aortic valve replacement is a potential option for patients who meet criteria for valve replacement[11] and who need prompt noncardiac surgery.

Pulmonary Hypertension

Pulmonary hypertension (Chapter 69) is a risk for cardiac and respiratory complications of surgery, and it is increasingly noted as a comorbid condition in patients who are undergoing bariatric surgery and who often have obstructive sleep apnea. However, no specific interventions are of proven value.

Hypertension and Arrhythmias

Hypertension (Chapter 64) is a common preoperative and postoperative issue for the medical consultant but only very rarely is a reason for delaying or canceling surgery unless it is associated with acute symptoms or end-organ sequelae. Intensification of blood pressure medications during the acute hospital phase may be associated with worse post-hospital and long-term outcomes, so changing medications in patients with mild to moderate asymptomatic hypertension is rarely warranted.

Arrhythmias are often a marker of underlying heart disease, and patients with preoperative atrial fibrillation have about a 30% increased risk of stroke and all-cause mortality.[12] Patients with pacemakers or implanted cardioverter defibrillators also have increased risks based on their underlying cardiac disease. No changes in therapy are warranted preoperatively, unless the rhythm abnormality would require it otherwise, but electrocardiographic monitoring may sometimes be warranted preoperatively.

PULMONARY RISK

The evaluation of patients' risk for perioperative pulmonary complications (e.g., postoperative pneumonia, respiratory failure, or reintubation) should begin with a thorough medical history and physical examination, with the goal of gathering information, including symptoms and functional status, needed to estimate risks using a validated index.[13] However, sleep apnea (Chapter 374) is often asymptomatic or less well recognized than asthma or chronic bronchitis, so particular attention should be paid to determining whether it is present using validated approaches.

Chronic obstructive pulmonary disease (Chapter 76) increases postoperative pulmonary complications by about two-fold, but well-controlled asthma (Chapter 75) does not appreciably increase risk. Active smoking increases risk, and smoking cessation is recommended for 4 to 8 weeks prior to surgery.

Key predictors of complications include the use of general anesthesia and proximity of the surgical site to the diaphragm. Intrathoracic and upper abdominal procedures decrease pulmonary function by approximately 50% and lower abdominal surgery by about 25%, with function not fully returning to normal for several weeks. Laparoscopic procedures and epidural or spinal anesthesia appear to be associated with a somewhat decreased risk for pulmonary complications.

Several indices, each using similar clinical features, are available to predict postoperative pulmonary complications. The surgical approach and the duration of surgery are independent risk factors in each risk index. The most commonly used approach (Table 399-5) divides patients undergoing general anesthesia into three risk categories based on age, preoperative oxygen saturation, recent pulmonary infection, preoperative hemoglobin level, site of surgery, and expected duration of surgery.

Preoperative Testing

Pulmonary function tests, arterial blood gases, and chest radiography are generally not indicated to assess perioperative pulmonary risk, unless the patient has new or unstable respiratory symptoms. Pulmonary function tests are routinely recommended, however, in surgical planning for lung reduction or resection surgeries to identify residual lung reserve and the feasibility of the surgery itself.

When the respiratory risk is high, changes in surgical technique (e.g., laparoscopic vs. open) or anesthetic approach (e.g., regional versus general anesthesia) should be considered. Preoperative respiratory muscle training is promising[A5] but not widely available. Patients should be encouraged to discontinue smoking at least 8 weeks before surgery, and nicotine replacement therapy should be prescribed if they continue to experience cravings at the time of surgery. Courses of corticosteroids or antibiotics for patients with otherwise stable chronic bronchitis are not indicated and may worsen clinical outcomes.

Patients at higher risk (>2%) for major pulmonary complications may be candidates for further attention, particularly postoperatively. Patients with sleep apnea may be candidates for modified pain regimens or continuous pulse oximetry after surgery.

Inhaled β-agonists or anticholinergics agents may be useful in reducing bronchospasm and improving patients' ability to ventilate and clear secretions. Lung expansion maneuvers, such as incentive spirometry, are useful if performed several times per hour, so they are less effective in patients who are somnolent, in pain, or have difficulty managing the device because of drains or intravenous catheters. Methods for lung expansion and airway clearance using positive airway pressure should be considered when available. Medical consultants can also aid in management of respiratory risk by encouraging the use of nonopioid pain regimens (see Table 26-4), orders for positioning and activity, and consideration of more aggressive monitoring (e.g., step-down unit or continuous pulse oximetry) in selected patients.

TABLE 399-5 ARISCAT* RISK INDEX: INDEPENDENT PREDICTORS OF POSTOPERATIVE PULMONARY COMPLICATIONS

FACTOR	POINTS
AGE, YEARS	
<50	0
51-80	3
>80	16

NEUROLOGIC RISK

STROKE

Postoperative stroke is infrequent in noncardiac surgery but highly morbid and associated with high mortality. Most postoperative strokes are ischemic in nature and result from emboli owing to the surgery itself (e.g., after carotid endarterectomy or cardiac surgery requiring cardiopulmonary bypass), intraoperative or postoperative hypotension,[14] or cardiac events (e.g., atrial fibrillation) that increase the risk of an embolic event. Though no risk index has been developed to target postoperative strokes per se, risk factors for stroke are similar to those for cardiac events.

Patients who have had a prior stroke have a markedly higher risk of postoperative strokes for 90 days[15] and perhaps for as long as 9 months after their initial cerebrovascular event, and elective surgery probably should be delayed in such patients. For patients who have asymptomatic high-grade extracranial carotid stenosis, guidelines for carotid revascularization (Chapter 376) should be followed before elective surgery. Thrombotic and embolic risks are the cornerstone of strategies around managing perioperative anticoagulants (covered elsewhere).

NEUROMUSCULAR DISEASE

Neuromuscular diseases (Chapters 386 to 390) have diverse underlying pathophysiologies but present with similar symptoms in terms of muscular

TABLE 399-6 RISK FACTORS FOR DELIRIUM

weakness or limited respiratory reserve. Some neuromuscular diseases involve other organs involvement (e.g., cardiac involvement Duchenne muscular dystrophy) that require specific monitoring. The complexity of these illnesses and the relationships among choices of anesthetics, the surgical approach, and the patient's baseline level of function require careful preoperative planning linked to postoperative monitoring, particularly for respiratory status.

DELIRIUM

Delirium (Chapter 361) is an important, common, and underrecognized complication of surgery. Delirium can lead to prolonged length of stay, additional in-hospital complications (e.g., pneumonia or thromboembolism), and worse post-hospital outcomes, including loss of independence, persistent cognitive impairment, and death. The medical consultant has a role in identifying patients at risk and recommending evidence-based strategies to reduce the incidence and severity of delirium.

Advancing age, functional status, and preoperative cognitive status are key features for predicting patients at increased risk of postoperative delirium (Table 399-6).[16] Patients with hip fractures are at particularly high risk largely because the risk factors for hip fracture (e.g., cognitive impairment, medical comorbidity, and functional decline) are closely associated with the risk of delirium.

Delirium, which is a clinical diagnosis (see Fig. 361-2), can range from agitation with active hallucinations to hypoactivity with somnolence. Furthermore, it waxes and wanes, thereby posing challenges for clinicians who see the patient at various times even during the same day. In the absence of traumatic head injury, falls in patients on anticoagulation, or newly noted focal neurologic findings, few tests are indicated for the diagnosis or evaluation of delirium in the preoperative time period. Laboratory risk factors for delirium (e.g., hyponatremia, hypercalcemia, or hypokalemia) should be corrected and monitored, but other tests (e.g., computed tomography of the brain, vitamin B_{12} levels) have no diagnostic or therapeutic role in the preoperative period.

TREATMENT AND PREVENTION

A key step in preventing and treating delirium is recognition of the disease itself and providing anticipatory guidance to the surgical team, patient, and family before surgery. Methods for prevention and treatment of delirium are multicomponent and multidisciplinary (Chapter 361),[A6] and the medical consultant has a key role in ensuring that effective treatments are used. Worthwhile intervention include active management of levels of serum electrolytes and glucose, use of supplemental oxygen if needed, implementing an effective bowel regimen, and ensuring that intravenous lines and catheters (particularly urinary catheters) are removed as early as feasible. Whenever possible, the consultant should attempt to discontinue medications that can worsen cognitive status (e.g., anticholinergic and antispasmodic medications). Nonopioid pain regimens (see Table 26-4), including scheduled acetaminophen and topical treatments (e.g., ice or warm compresses), can improve pain control without adding sedating medications.

Prehabilitation programs involving intensive presurgical physical therapy and comprehensive geriatric care programs[A7,A8] may improve functional recovery and may reduce the incidence and severity of delirium among older patients with functional limitations who are to undergo major surgery. Melatonin at low doses (2 to 5 mg) in the evening can aid with sleep and restore sleep–wake cycles that can be disturbed in the hospital setting. Ramelteon (a melatonin receptor/agonist at 8 mg nightly orally)[A9] or intravenous dexmedetomidine (0.1 μg/kg/hour) from intensive care unit admission on the day of surgery until 8 AM the next morning[A10] can reduce postoperative delirium. Prophylactic antipsychotic agents are not recommended, even in patients at risk for delirium.

Effective behavioral interventions can include instructing the nurses, care attendants, and patient's family to reorient the patient to day and time and to work to redirect the patient if the patient become agitated. Early and effective increases in mobility (e.g., getting the patient into a chair or walking every day) are helpful. In addition, many hospitals have specialized care units (sometimes called Acute Care for the Elderly units) for patients who have delirium and aging-related disorders; patients at high risk for postoperative delirium may benefit from care in these settings.

ENDOCRINE RISKS

DIABETES

Aggressive approaches to maintain a normal glucose level increase morbidity in most postoperative patients. The consultant's recommendations therefore should emphasize strategies that avoid in-hospital complications of diabetes, whether hypoglycemia or ketoacidosis, by targeting a blood sugar level between 80 and 140 mg/dL (Chapter 210).[17] Patients whose diabetes is controlled by diet alone can be managed with fingerstick blood glucose monitoring and short-acting insulin to correct hyperglycemia on an as-needed basis. Diabetic patients who take oral medications should not take them on the morning of surgery, with fingerstick monitoring and as-needed insulin in the immediate surgical period; postoperatively, such patients should continue with fingerstick monitoring and be treated with a combination of a short-acting insulin plus carefully titrated intermediate- or long-acting insulin, depending on daily basal insulin needs. Oral medications should be restarted prior to discharge if possible to ensure a smooth transition to home. Depending on their baseline blood glucose levels and the expected duration of surgery, patients with insulin-dependent diabetes typically should receive half to two thirds of their usual intermediate- or long-acting insulin dose prior to surgery, with a combination of their longer-acting insulin (usually at lower than home dose) and short-acting correctional insulin used in concert with frequent fingersticks to ensure good control after surgery. In patients who have insulin pumps, expert management by an endocrinologist is recommended.

GLUCOCORTICOIDS AND ADRENAL INSUFFICIENCY

Patients who are receiving less than 5 mg of prednisone (or its equivalent) daily or any dose of glucocorticoids for less than 3 weeks can continue this medication through the perioperative period (or forgo stress dose steroids). If the patient is to undergo a very low-risk procedure (e.g., dental extraction, cataract removal, arthroscopy), it is reasonable to continue the chronic glucocorticoid dose uninterrupted. Patients who have received higher doses for 3 weeks or longer or who are undergoing other surgeries are at increased risk for suppression of the hypothalamic–pituitary axis and should receive for stress dose corticosteroids, administered as hydrocortisone 50 to 100 mg IV prior to surgery. They then should receive either a 200-mg continuous infusion for 24 hours (Chapter 208)[18] or 50 to 100 mg every 8 hours for 1 day, followed by transition to their chronic dose (intravenously if required) on day 2.

THYROID DISORDERS

The major risks of thyroid disorders (Chapter 207) in the perioperative setting are for patients whose hypothyroidism or hyperthyroidism is poorly controlled or undiagnosed. Testing for thyroid disorders should be prompted by findings on the preoperative history and physical examination. If a patient has clinical hypothyroidism or hyperthyroidism and the surgery is elective, it is reasonable to delay the surgery to begin appropriate medical therapies needed to achieve euthyroidism before the surgery is performed. For urgent or emergent procedures, the hyperthyroid patient should be managed using accepted therapies for thyrotoxicosis (e.g., β-blockers, intravenous glucocorticoids; Chapter 207) with a goal of controlling the heart rate and reducing clinical signs of hyperthyroidism prior to surgery. For patients who have clinically apparent hypothyroidism prior to surgery, intravenous thyroxine (200 to 300 μg once, followed by 50 to 100 μg daily, with transition to oral maintenance dosing [see Chapter 207] at time of discharge) is a reasonable approach. Patients with clinically apparent hypothyroidism should also receive stress dose steroids for 24 hours after surgery.

RENAL, HEMATOLOGIC, AND LIVER DISORDERS

CHRONIC KIDNEY DISEASE

Patients with chronic kidney disease (Chapter 116) are at higher risk for a range of complications following surgery, in part because of the comorbid conditions that accompany chronic kidney disease, but also because of problems that result from chronic kidney disease itself (e.g., volume status, electrolyte management, anemia).[19] Few data support any approaches to reducing the risks of worsening renal function in patients with chronic kidney disease. The consultant should develop a plan to manage and monitor electrolytes in patients before and after surgery, with particular focus on diuretics and ensuring perioperative medications are dosed at levels that are appropriate for the degree of renal impairment. Patients on hemodialysis should have a dialysis treatment the morning of surgery to ensure adequate volume and electrolyte balance;[20] postoperative dialysis treatments can be performed as scheduled or tailored based on the patient's ability to produce urine, intrinsic renal function (e.g., ability manage electrolytes and acid-base status), and surgical factors (e.g., volume loss or administration during surgery).

ANEMIA AND CLOTTING PROBLEMS

Although preoperative anemia is a risk factor for 30-day complications, strong evidence supports a restrictive transfusion approach in patients who require surgery emergently or urgently. In these patients, transfusion should be triggered by a hemoglobin level of 7 g/dL if the patient is otherwise asymptomatic. For patients with cardiopulmonary symptoms, known cardiopulmonary disease, or undergoing major surgery, a transfusion threshold of 9 to 10 g/dL is appropriate.[A11] Preoperative iron therapy does not reduce risks.[A12] Patients who have significant anemia and who are scheduled for elective surgery should undergo routine evaluation (Chapter 144) prior to surgery, with the goal of ensuring that no life- or prognosis-limiting problems (e.g., active gastrointestinal bleeding or advanced gastrointestinal cancer) coexist with the surgical problem. In patients undergoing noncardiac surgery, tranexamic acid administered by the surgical team can reduce bleeding events.[A13]

LIVER DISEASE

Patients with asymptomatic or mild chronic hepatitis or other liver disease do not require specific preoperative testing beyond what is routinely indicated. However, such patients may be at higher risk for postoperative complications due in part to the causes of their liver disease (e.g., delirium in patients with alcohol-related hepatitis).[21] Outcomes of patients with cirrhosis tend to correlate with the severity of their liver disease as quantified by Model for End-Stage Liver Disease (MELD) score (Table 139-2). The focus in such patients should be on managing volume status (particularly ascites), clotting disorders, and potential encephalopathy (Chapter 139).

APPROACH TO MANAGING MEDICATIONS

CHRONIC MEDICATIONS

The management of medication is a key aspect of the preoperative consultation, with an emphasis on identifying which medications should have their doses modified or be discontinued (and if so, for how long) during the surgical period (Table 399-7) and being sure that needed medications be restarted before the patient is discharged or before the first postoperative visit. Medications should be stopped or have their doses modified if they have a direct relationship with surgical complications (e.g., warfarin and bleeding) or cannot be safely administered in the perioperative period (e.g., the patient is not eating, so modified doses of insulin are required).

Most medications should be continued as is feasible (based on patient's ability to take oral medications or their volume status) during the hospitalization. For insulin-dependent diabetes, adjustments in the insulin dose are critical (see earlier). For patients who are taking chronic glucocorticoids, stress doses are recommended (see earlier). Conversely, a subset of medications (e.g., angiotensin-converting enzyme inhibitors) are usually discontinued temporarily during the perioperative period because they can produce transient problems during the induction of anesthesia or while the patient is unable to eat. In these cases, the key goal is to ensure that medications are restarted prior to discharge.

The most challenging perioperative medication issue relates to antiplatelet agents and anticoagulants because the risk of perioperative bleeding must be balanced against the risk of thrombotic events. Most procedures outside of the central nervous system and spine can be performed safely while continuing

TABLE 399-7 APPROACH TO COMMON LONGITUDINAL MEDICATIONS IN THE PERIOPERATIVE PERIOD

	GENERAL APPROACH
CARDIOVASCULAR	
• β-Blockers and clonidine	Occasionally stopped by anesthesiologist on day of surgery based on concerns for hypotension during induction of anesthesia; medical consultant should focus on continuity through perioperative period
• Calcium channel blockers	No data to support holding or discontinuing; medical consultant should focus on continuity through perioperative period
• Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers	Occasionally stopped by anesthesiologist on day of surgery based on concerns for hypotension during induction of anesthesia; medical consultant should focus on continuity through perioperative period
• Statins	Some data suggest continuity can reduce risk for cardiovascular events; medical consultant should focus on continuity through perioperative period
• Diuretics	Can be held based on volume status or anticipated blood loss; medical consultant should focus on continuity through perioperative period
• Antiarrhythmic agents	No data to support holding or discontinuing; medical consultant should focus on continuity through perioperative period
GASTROINTESTINAL	
• Proton-pump inhibitors and histamine-2 blockers	No data to support holding or discontinuing; medical consultant should focus on continuity through perioperative period
PULMONARY	
• Inhaled medications	No data to support holding or discontinuing; medical consultant should focus on continuity through perioperative period
• Oral medications	No data to support holding or discontinuing; medical consultant should focus on continuity through perioperative period
ENDOCRINE	
• Oral hypoglycemic agents	Hold on day of surgery; replace with subcutaneous insulin until taking full diet (Chapter 210)
• Injected hypoglycemic agents	Exenatide, liraglutide: hold on day of surgery to avoid slowing gastric emptying; sitagliptin, linagliptin: can be continued (Chapter 210)
• Insulin	Type II diabetes: discontinue long-acting insulin 24 hours before surgery, administer reduced dose (usually half to two-thirds) of short-acting insulin on day of surgery, restart after surgery; type I diabetes: continue basal insulin through surgery (see Chapter 210 and text)
• Glucocorticoids	Consider stress dose corticosteroids if on chronic corticosteroids (see Chapter 208 and text)
• Estrogens	Consider discontinuation before surgery in patients at risk for thromboembolism
• Thyroid medications	Continue through surgery
HEMATOLOGIC AGENTS	
• Antiplatelet agents	See text and Fig. 399-3
• Anticoagulants	See text and Fig. 399-3
PSYCHIATRIC MEDICATIONS	In general, continue through surgical period. Monoamine oxidase inhibitors infrequent but should be held 10-14 days before surgery
OPIOIDS	No data to support holding or discontinuing; medical consultant should focus on continuity through perioperative period and anticipate an increment in the required dose due to acute postsurgical pain

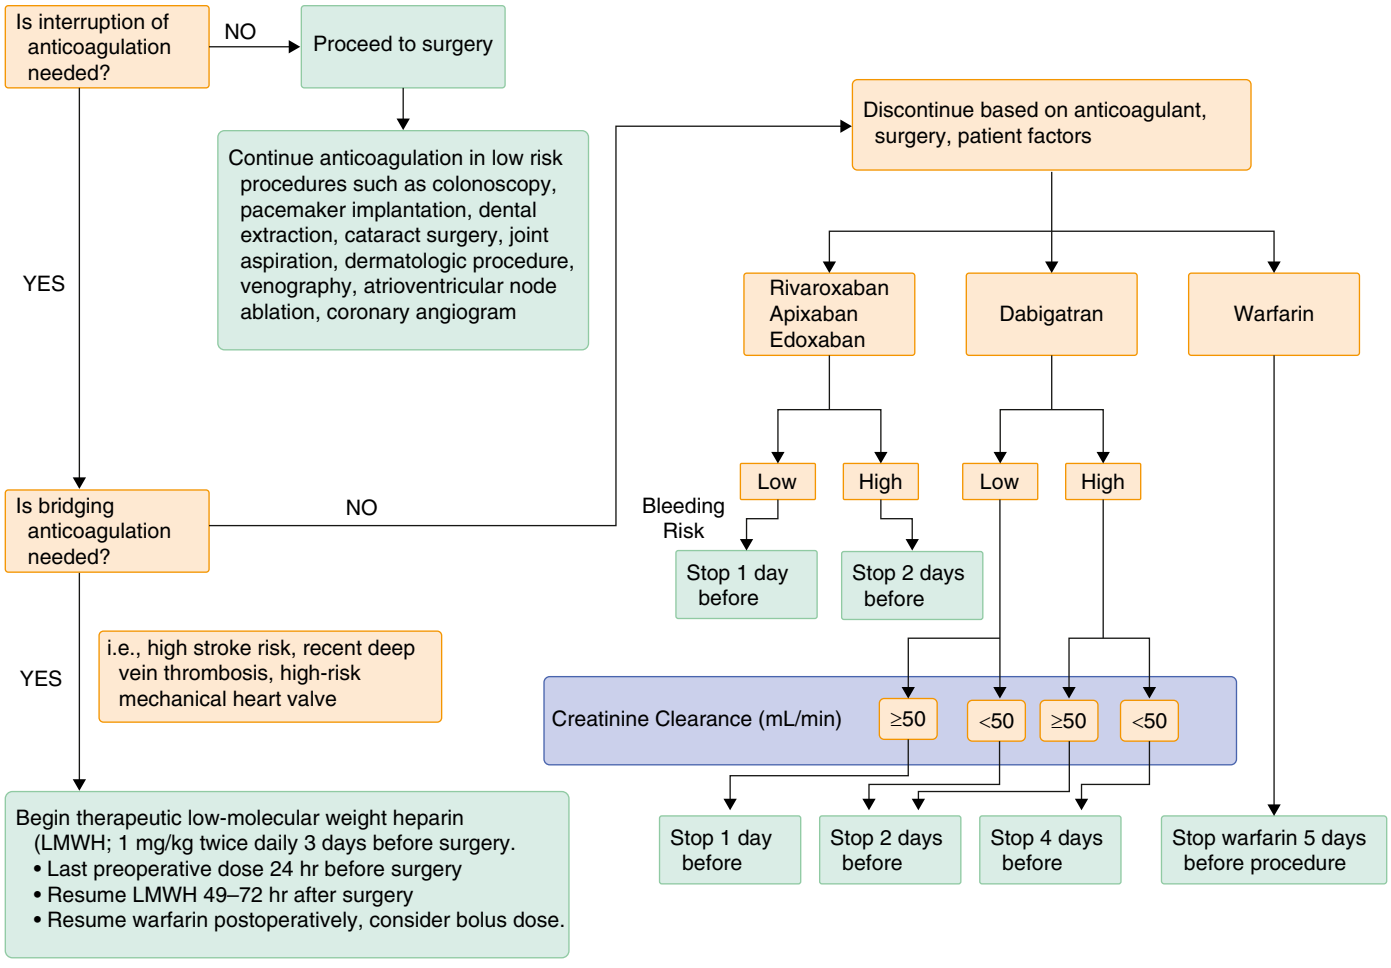

FIGURE 399-3. Anticoagulation management in the perioperative time period. DOAC = direct-acting oral anticoagulant; LMWH = low molecular weight heparin. (Adapted from Tafur A, Douketis J. Perioperative management of anticoagulant and antiplatelet therapy. *Heart*. 2018;104:1461-1467; and Douketis JD, Spyropoulos AC, Duncan J, et al. Perioperative management of patients with atrial fibrillation receiving a direct oral anticoagulant. *JAMA Intern Med*. 2019;179:1469-1478.)

low-dose (81 mg daily) aspirin through the perioperative period. The decision to hold other antiplatelet agents (see Table 70-8) such as clopidogrel (5 to 7 days before surgery), ticagrelor (5 days), or prasugrel (7 days) depends on risks of bleeding due to the procedure and the indication for the antiplatelet agent (e.g., cardiac stent). In cases in which P2Y12 inhibitors can be held (e.g., drug-eluting stent at least 6 and optimally 12 months old), aspirin should be continued, with the PY12 inhibitor restarted as soon as feasible after the procedure. If aspirin must be stopped, it should be discontinued 5 to 7 days before the planned procedure. If a drug-eluting cardiac stent is less than 6 months old, the patient is planned for urgent or emergent surgery, and dual antiplatelet therapy cannot be safely held for other reasons, few data exist to describe optimal management, though intravenous IIb/IIIa inhibitors could be considered as a bridge through the perioperative period (see Chapter 70 and Table 70-8).

For oral anticoagulants, low-risk patients (e.g., patients with distant history of thromboembolism) and patients with atrial fibrillation do not require bridging anticoagulation and should have their anticoagulant discontinued prior to surgery,[A14] with the time period depending on the medication, the patient's renal function, and the planned surgical procedure (see Fig. 399-2).[22,23] Even in the absence of data from randomized trials, patients who are at highest risk of thromboembolism while off anticoagulation (e.g., a mechanical mitral valve, known atrial appendage clot, or pulmonary embolism within the last 3 months) should have bridging anticoagulation with low-molecular-weight heparin (LMWH 1 mg/kg twice daily) or unfractionated heparin (Table 70-3), with these agents held for 24 hours (LMWH) or 6 hours (unfractionated heparin) prior to surgery.[24] Either agent should be restarted at therapeutic doses as soon as safe (optimally 24 hours) after surgery, with the patient's oral agent restarted soon thereafter. Many patients may have risks in between these two groups and will require a tailored approach, but the preponderance of evidence suggests that bridging anticoagulation strategies, though effective at reducing thrombosis and thromboembolism, are associated with excess bleeding and should not be used or must be used judiciously as part of a comprehensive plan. For example, if a patient has had a recent embolic event, it may be reasonable to delay the surgery until the patient has been on therapeutic anticoagulation for 12 or more weeks. If the surgery cannot be delayed, a temporary inferior vena cava filter may be indicated for patients with recent venous thromboembolism.

COMMUNICATING WITH THE SURGEON AND ANESTHESIOLOGIST

A consultant's recommendations should answer any specific questions posed by the consulting surgeon, while also relaying an overall assessment and key conclusions to the surgeon and the patient (Table 398-2). Terms such as "cleared for surgery" are nonspecific and unhelpful. Instead, the patient can be classified as being at "acceptable risk" when concerns are minimal, "elevated but acceptable risk" when additional preoperative recommendations are tailored to reduce risks, or "very high/concerning" when risks of complications are relatively high and intensified postoperative monitoring is required. The consultant should also use risk indices or disease-specific evaluations to describe the patient's primary sources of risk (e.g., cardiac risk, or pulmonary risk), followed by specific recommendations that correlate with the areas of risk as well as contingency plans should unexpected findings or events take place.

The consultant should also consider recommendations to ensure standard safety and quality steps are followed after surgery (e.g., thromboembolism prophylaxis, early removal of urinary catheters, and opioid-sparing pain regimens; see Chapter 401). Finally, the consultant should ensure close coordination of care by determining what postoperative role (e.g., continued consultation, active comanagement) is desired.

400 OVERVIEW OF ANESTHESIA

JEANINE P. WIENER-KRONISH AND LEE A. FLEISHER

Approximately 300 million interventional procedures are performed worldwide each year. Anesthetics and/or sedation and analgesia are utilized for most of these procedures, almost half of which are performed outside of a hospital operating room. Deaths attributed to anesthesia are very rare, estimated between 1:10,000 and 1:200,000.[1,2]

Risk reduction over recent decades has been a result of mandatory preoperative assessments, of functional status, cardiopulmonary disease, frailty,[3–5] and neuromuscular disease; attempts to achieve smoking cessation, alcohol abstinence, and control of opioid use; better intraoperative systems[6,7,A1]; and improved postoperative care. Preoperative fasting reduces the risk of aspiration, but clear liquids may be ingested up until arrival in the operating room without obvious adverse effects.[8] The location of care can also impact surgical outcomes, with teaching hospitals having superior outcomes in multimorbid patients.[9]

PREOPERATIVE ASSESSMENT

Essential aspects of total preoperative risk assessment (Chapter 399) include the type of surgery or procedure to be performed, the patient's underlying medical conditions, including dementia,[10] their functional state, and any specific issues related to the patient and the procedure.[11] Frailty, malnutrition, and sarcopenia are now recognized as important features that affect perioperative outcomes. Additionally, the preoperative evaluation can be used as a means to improve long-term health as part of a population health strategy.

AIRWAY ASSESSMENT

Assessment of the airway is always necessary, even if regional anesthesia or monitored anesthesia care (local anesthesia with sedation) is planned, because unexpected complications or compromise of airway reflexes may lead to an emergent need to support ventilation. The laryngeal mask airway device allows many patients to be ventilated easily, but it is important to assess the ability to intubate the patient as well as the ability to ventilate. The prevalence of difficult intubation is about 6% for nonobese patients, and reasons for difficulty include airway pathology (e.g., tumors, previous surgery), reduced mobility of the cervical spine, obstructive sleep apnea, or the anatomic relationship between the larynx and trachea. Although the videolaryngoscope offers improved views of the larynx and is used in many patients who need difficult or emergent intubation,[A2] the device does not improve success in nonexpert hands, nor does its use prevent complications.[A3] Difficult intubations can best be accomplished by clinicians who are expert in airways and who can personalize the choice among the various methods for intubation.[A4]

Criteria for extubation in postoperative patients are similar to those in other patients who receive mechanical ventilation (Chapter 91). Older patients with more severe, comorbid diseases, especially underlying cardiac or pulmonary disease, are more likely to require postoperative reintubation, which is associated with a nine-fold increase in mortality.

MEDICATION REACTIONS

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (Chapter 402), which is a result of calcium dysregulation in skeletal muscle cells, leads to an increase in the production of carbon dioxide, increased oxygen consumption, and the production of heat during or immediately after exposure to triggering drugs, including halogenated volatile anesthetics and/or the depolarizing muscle relaxant, succinylcholine. Variations in the ryanodine receptors that regulate the duration and amplitude of calcium efflux from the sarcoplasmic reticulum are the leading cause of malignant hyperthermia, but variations in other genes (including *CACNA1S* and *STAC3*) also can predispose (Chapter 99).[12] Such genetic variants affect between 1:400 and 1:8500 people. Patients with mutations predisposing to malignant hyperthermia can function normally at resting conditions, but exposure to volatile anesthetics, or exposure to a succinylcholine, can precipitate life-threatening muscle contractures, increases in heart rate and body temperature, rhabdomyolysis, myoglobinuria, and metabolic acidosis. The mortality rate is 80% in untreated patients but about 5% with current treatment. Patients with malignant hyperthermia do not predictably respond to triggering agents, and some patients with malignant hyperthermia have had milder symptoms after the administration of nontriggering agents. Malignant hyperthermia now often occurs in muted forms, probably because of the decreased use of succinylcholine, the diagnostic awareness of malignant hyperthermia by anesthesiologists, the routine use of carbon dioxide monitors so that increases in end-expiratory carbon dioxide are detected quickly, and the availability of dantrolene. If malignant hyperthermia is suspected by obtaining a family history of adverse events with the administration of anesthesia or when a patient has a reaction suspicious for malignant hyperthermia, a muscle biopsy is usually obtained for in vitro contracture testing, which evaluates the muscle contracture responses to caffeine or halothane. Genetic investigations are also recommended, but malignant hyperthermia cannot be excluded on the basis of genetic testing alone because of the diversity of mutations and genes that can be involved in this syndrome. Medical personnel can get information 24 hours a day (www.mhaus.org or on the malignant hyperthermia hotline, 1-800-MHHYPER or 1-800-644-9737).

Rare congenital myopathies that are associated with mutations of the *RYR1* gene, which encodes the ryanodine receptor, and with the malignant hyperthermia syndrome include central core disease and multi/minicore disease, both of which present in early childhood. The clinical spectrum of *RYR1* mutations associated with malignant hyperthermia syndrome includes exertional myalgia associated with rhabdomyolysis, periodic paralysis, and a late-onset axial myopathy. Severe hyperkalemia and cardiac arrest also can be seen after the administration of succinylcholine in patients with other muscular dystrophies, such as Duchenne muscular dystrophy.

TREATMENT

Dantrolene, which is the drug of choice to prevent and reverse the symptoms of malignant hyperthermia, decreases muscle sensitivity to caffeine, reduces the release of calcium from the sarcoplasmic reticulum, and produces some muscle weakness. The dose of dantrolene should be 2 to 2.5 mg/kg, repeated

400 OVERVIEW OF ANESTHESIA

JEANINE P. WIENER-KRONISH AND LEE A. FLEISHER

Approximately 300 million interventional procedures are performed worldwide each year. Anesthetics and/or sedation and analgesia are utilized for most of these procedures, almost half of which are performed outside of a hospital operating room. Deaths attributed to anesthesia are very rare, estimated between 1:10,000 and 1:200,000.[1,2]

Risk reduction over recent decades has been a result of mandatory preoperative assessments, of functional status, cardiopulmonary disease, frailty,[3–5] and neuromuscular disease; attempts to achieve smoking cessation, alcohol abstinence, and control of opioid use; better intraoperative systems[6,7,A1]; and improved postoperative care. Preoperative fasting reduces the risk of aspiration, but clear liquids may be ingested up until arrival in the operating room without obvious adverse effects.[8] The location of care can also impact surgical outcomes, with teaching hospitals having superior outcomes in multimorbid patients.[9]

PREOPERATIVE ASSESSMENT

Essential aspects of total preoperative risk assessment (Chapter 399) include the type of surgery or procedure to be performed, the patient's underlying medical conditions, including dementia,[10] their functional state, and any specific issues related to the patient and the procedure.[11] Frailty, malnutrition, and sarcopenia are now recognized as important features that affect perioperative outcomes. Additionally, the preoperative evaluation can be used as a means to improve long-term health as part of a population health strategy.

AIRWAY ASSESSMENT

Assessment of the airway is always necessary, even if regional anesthesia or monitored anesthesia care (local anesthesia with sedation) is planned, because unexpected complications or compromise of airway reflexes may lead to an emergent need to support ventilation. The laryngeal mask airway device allows many patients to be ventilated easily, but it is important to assess the ability to intubate the patient as well as the ability to ventilate. The prevalence of difficult intubation is about 6% for nonobese patients, and reasons for difficulty include airway pathology (e.g., tumors, previous surgery), reduced mobility of the cervical spine, obstructive sleep apnea, or the anatomic relationship between the larynx and trachea. Although the videolaryngoscope offers improved views of the larynx and is used in many patients who need difficult or emergent intubation,[A2] the device does not improve success in nonexpert hands, nor does its use prevent complications.[A3] Difficult intubations can best be accomplished by clinicians who are expert in airways and who can personalize the choice among the various methods for intubation.[A4]

Criteria for extubation in postoperative patients are similar to those in other patients who receive mechanical ventilation (Chapter 91). Older patients with more severe, comorbid diseases, especially underlying cardiac or pulmonary disease, are more likely to require postoperative reintubation, which is associated with a nine-fold increase in mortality.

MEDICATION REACTIONS

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (Chapter 402), which is a result of calcium dysregulation in skeletal muscle cells, leads to an increase in the production of carbon dioxide, increased oxygen consumption, and the production of heat during or immediately after exposure to triggering drugs, including halogenated volatile anesthetics and/or the depolarizing muscle relaxant, succinylcholine. Variations in the ryanodine receptors that regulate the duration and amplitude of calcium efflux from the sarcoplasmic reticulum are the leading cause of malignant hyperthermia, but variations in other genes (including *CACNA1S* and *STAC3*) also can predispose (Chapter 99).[12] Such genetic variants affect between 1:400 and 1:8500 people. Patients with mutations predisposing to malignant hyperthermia can function normally at resting conditions, but exposure to volatile anesthetics, or exposure to a succinylcholine, can precipitate life-threatening muscle contractures, increases in heart rate and body temperature, rhabdomyolysis, myoglobinuria, and metabolic acidosis. The mortality rate is 80% in untreated patients but about 5% with current treatment. Patients with malignant hyperthermia do not predictably respond to triggering agents, and some patients with malignant hyperthermia have had milder symptoms after the administration of nontriggering agents. Malignant hyperthermia now often occurs in muted forms, probably because of the decreased use of succinylcholine, the diagnostic awareness of malignant hyperthermia by anesthesiologists, the routine use of carbon dioxide monitors so that increases in end-expiratory carbon dioxide are detected quickly, and the availability of dantrolene. If malignant hyperthermia is suspected by obtaining a family history of adverse events with the administration of anesthesia or when a patient has a reaction suspicious for malignant hyperthermia, a muscle biopsy is usually obtained for in vitro contracture testing, which evaluates the muscle contracture responses to caffeine or halothane. Genetic investigations are also recommended, but malignant hyperthermia cannot be excluded on the basis of genetic testing alone because of the diversity of mutations and genes that can be involved in this syndrome. Medical personnel can get information 24 hours a day (www.mhaus.org or on the malignant hyperthermia hotline, 1-800-MHHYPER or 1-800-644-9737).

Rare congenital myopathies that are associated with mutations of the *RYR1* gene, which encodes the ryanodine receptor, and with the malignant hyperthermia syndrome include central core disease and multi/minicore disease, both of which present in early childhood. The clinical spectrum of *RYR1* mutations associated with malignant hyperthermia syndrome includes exertional myalgia associated with rhabdomyolysis, periodic paralysis, and a late-onset axial myopathy. Severe hyperkalemia and cardiac arrest also can be seen after the administration of succinylcholine in patients with other muscular dystrophies, such as Duchenne muscular dystrophy.

TREATMENT

Dantrolene, which is the drug of choice to prevent and reverse the symptoms of malignant hyperthermia, decreases muscle sensitivity to caffeine, reduces the release of calcium from the sarcoplasmic reticulum, and produces some muscle weakness. The dose of dantrolene should be 2 to 2.5 mg/kg, repeated

ABSTRACT

In the United States, 40 million procedures per year require an anesthetic. This chapter reviews the ongoing evolution of risk assessment, the advantages and disadvantages of general compared with regional anesthesia, the major risk factors for adverse clinical outcomes, the medication reactions that can occur during anesthesia (including malignant hyperthermia and serotonin toxicity), and how the pharmacology and toxicity of common parenteral anesthetics and opioids can affect the postoperative course.

dexmedetomidine

every 10 minutes until all signs regress, even if the dose exceeds 10 mg/kg. Dantrolene should be stopped when a normal minute ventilation is achieved and the core temperature is decreasing.

Other treatments for malignant hyperthermia include discontinuing the use of any volatile anesthetics; hyperventilating the patient and administering 100% oxygen; administering bicarbonate for severe acidosis; controlling fevers; and maintaining a temperature below 39° C without causing hypothermia by using iced fluids, surface cooling, and cooling of body cavities if necessary. The patient's temperature and vital signs, urinary output, muscle enzymes, glucose, coagulation studies, acid-base status, and gas exchange should be monitored for 48 hours and be observed for 72 hours to ensure there is no recrudescence.

MONOAMINE OXIDASE INHIBITORS AND SEROTONIN TOXICITY

The severe serotonin syndrome is usually precipitated when two or more serotonic drugs are administered, but the syndrome can occur with the administration of one such medication in a susceptible individual.[13] Serotonin toxicity has features similar to malignant hyperthermia and must be distinguished from it. Serotonin toxicity is characterized as a triad of neuromuscular hyperactivity (tremor, clonus, myoclonus, hyperreflexia, and pyramidal rigidity), autonomic hyperactivity (diaphoresis, fever, tachycardia, and tachypnea), and altered mental status (agitation, excitement, and confusion). It can be precipitated by the coadministration of monoamine oxidase inhibitors and selective serotonin reuptake inhibitors (SSRIs). Patients who are taking SSRIs have a higher overall perioperative mortality, a higher 30-day readmission rate, and a higher likelihood of bleeding. Rigidity, increasing arterial carbon dioxide levels, and fever above 38.5° C are associated with life-threatening toxicity. Ecstasy, or 3,4-methylenedioxymethamphetamine (MDMA), combined with monoamine oxidase inhibitors, including moclobemide, can be fatal because it acts as a serotonin releaser. Tramadol, used for pain relief, and venlafaxine, an antidepressant, act as serotonin releasers and are associated with toxicity when used in patients who are taking monoamine oxidase inhibitors. Patients with Parkinson disease are increasingly prescribed monoamine oxidase-B (MAO-B) inhibitors, and a dyskinesia-hyperpyrexia syndrome can occur in these patients.[14]

ANAPHYLAXIS IN THE PERIOPERATIVE PERIOD

The incidence of life-threatening hypersensitivity reactions during anesthesia is 1 : 4000 to 1 : 25,000. Anaphylaxis is caused by immunoglobulin E (IgE)–mediated reactions (Chapter 233), whereas anaphylactoid reactions produce the same clinical picture but are not mediated by IgE. Anaphylaxis during anesthesia can present as cardiovascular collapse, airway obstruction, flushing, or edema of the skin, singly or in combination, so a careful history of any previous allergic reactions to medications and the nature of the reaction must be obtained by the anesthesiologist and other members of the perioperative team. Neuromuscular blocking agents, such as succinylcholine, and opioid analgesics can cause nonimmunologic release of histamine from mast cells and produce a similar clinical syndrome. Antibiotics, protamine, and blood transfusions (Chapter 162), all given routinely during operations, also can elicit a variety of systemic reactions. About 75% of perioperative hypersensitivity reactions appear to be due to muscle relaxants, especially rocuronium and vecuronium, with a mortality rate of 3 to 6%. In patients with apparent allergic reactions, skin testing is usually performed, and IgE levels are usually obtained to determine whether the patient had an allergic reaction to a perioperative medication.

SODIUM-GLUCOSE COTRANSPORTER-2 INHIBITORS AND DIABETIC KETOACIDOSIS

Patients with type 2 diabetes and chronic kidney disease (Chapters 109, 116, and 210) or with heart failure (Chapter 46) have a lower risk of death from cardiovascular causes when treated with sodium-glucose cotransporter 2 inhibitors. The decreased fluid intake prior to and after anesthesia and surgery may predispose patients on these medications to dehydration, ketogenesis, and diabetic ketoacidosis. These drugs should be discontinued 3 to 4 days prior to major surgery, especially if bowel preparation is needed.[15]

LATEX ALLERGY

For sensitized patients (Chapter 233), exposure to even low amounts of latex-containing particles is sufficient to induce a severe anaphylactic reaction. A latex-free operating environment, in which no latex gloves or latex accessories are used, is key in patients with known allergy. Skin prick tests with latex extracts should be considered in patients at high risk for latex allergy. Early aggressive treatment with epinephrine is critical if severe anaphylaxis occurs.

TABLE 400-1 COMMON ANESTHETIC APPROACHES FOR VARIOUS TYPES OF SURGERY

SURGERY ON INTRA-ABDOMINAL OR INTRATHORACIC ORGANS
Examples: cardiac surgery, lung resections, gastric bypass
General anesthesia usually administered because mechanical ventilation is often required
Drugs include premedication for anxiety with midazolam, general anesthesia with volatile anesthetics (desflurane, sevoflurane, nitrous oxide), neuromuscular blockade, and opioid analgesics*
Epidural anesthesia and analgesia also used; examples include ropivacaine, lidocaine, with fentanyl
SURGERY ON LIMBS
Examples: hip replacement, knee replacement, foot or arm surgery
Can perform with epidural or spinal anesthesia, depending on the limb. Examples of medications would include tetracaine, lidocaine, ropivacaine, and fentanyl or morphine
Can perform axillary or scalene block; examples include lidocaine and ropivacaine
For postoperative pain control: can perform regional blocks that leave the catheter in place, including femoral nerve block, axillary nerve blocks
CATARACT SURGERY—LOCAL ANESTHESIA ON EYE WITH OR WITHOUT SEDATION†
Examples of drugs used for sedation include midazolam and fentanyl

*Includes the use of opioids given intraoperatively with effects that extend into the postanesthesia care unit (PACU) or postoperative period, opioids given in the PACU, or opioids given or intended to be given after discharge from the PACU.

†Anesthesia personnel are involved in the majority of cataract procedures, thereby suggesting that either blocks and/or local anesthesia with sedation are being utilized for the majority of cataract procedures.

INTRAOPERATIVE MANAGEMENT

There are three general classes of anesthesia: general, regional, and monitored anesthesia care. The same drugs are often used for general anesthesia and monitored anesthesia care; achievement of the two different conditions requires knowledge of the pharmacokinetics of the drugs (Table 400-1).

GENERAL ANESTHESIA

General anesthesia can be achieved with a balanced drug regimen that induces a loss of consciousness, which can range from a deep sedation requiring only airway support to states requiring full ventilatory support because of weakness and loss of respiratory drive. Both intravenous[16] and inhalational drugs can be used to induce and maintain general anesthesia. In contrast, monitored anesthesia care denotes a state in which patients can still control their airway, do not require ventilatory support, but are sleepy, have less pain, and may be amnestic. The quantity of anesthesia required to achieve unconsciousness varies depending on the patient's brain function and can be titrated by using electroencephalography.[17] Some data suggest that a lighter depth of anesthesia may be associated with less postoperative delirium[A5]

For general anesthesia, adequate and safe ventilation is critical. On average, there is no benefit from high as compared with low tidal volume or end-expiratory pressures,[A6,A7] so tidal volumes and end-expiratory pressures should be individualized for specific patients.[18]

Robotic-assisted laparoscopic surgeries, especially in obese patients, adversely affect respiratory mechanics intraoperatively because of abdominal insufflation and Trendelenburg positioning.[19,20] In patients undergoing these procedures, the use of electrical impedance tomography and of individualized positive end-expiratory pressures can improve the homogeneity of ventilation and reduce postoperative pulmonary complications.

PROPOFOL

Propofol, an alkylphenol, is perhaps the most frequently used intravenous anesthetic for induction of anesthesia and is often used for maintenance of anesthesia during short procedures or to achieve deep sedation during monitored anesthesia care. It is lipid soluble and quickly cleared from the central compartment, so it is rapidly eliminated even after long periods of continuous infusion. However, the clearance of propofol is changed by gender (men have lower clearance rates than women), size (children require higher doses), age (elderly patients have decreased clearance rates and experience increased effects with the drug), and narcotics, which decrease its clearance. Because of its predilection for causing apnea, propofol should be administered only

by someone with expertise in airway management. Propofol also decreases arterial blood pressure, causes pain with injection, and can precipitate myoclonus. Large quantities of propofol can cause propofol infusion syndrome, which is associated with cardiomyopathy, metabolic acidosis, skeletal myopathy, hyperkalemia, hepatomegaly, and lipemia. Despite these issues, propofol is frequently used because the recovery from propofol is within minutes, even after it is given as a prolonged continuous infusion, in contrast to the longer duration of drug effects seen after the administration of other intravenous sedatives. Propofol is commonly the preferred agent for healthy outpatients undergoing colonoscopy because it leads to earlier discharge and higher patient satisfaction compared with other agents.

MIDAZOLAM

Midazolam, a benzodiazepine that produces muscle relaxation through a central mechanism, is hypnotic, sedative, anxiolytic, amnesic, and anticonvulsant. Its amnesic and anticonvulsant effects are mediated through α_1-subunit–containing γ-aminobutyric acid A ($GABA_A$) receptors, and the anxiolytic and muscle relaxation are mediated through α_2-subunit–containing $GABA_A$ receptors. Only 20% receptor occupancy is needed to produce anxiolysis, whereas unconsciousness requires 60%. Long-term administration of benzodiazepines produces tolerance, which appears to decrease receptor binding and function. Benzodiazepines cause dose-related depression of the respiratory system, with a peak effect at 3 minutes and significant depression persisting for 60 to 120 minutes. The rate of administration of the drug affects the onset of depression: the faster the drug is given, the quicker the respiratory depression occurs. Benzodiazepines and opioids appear to produce additive respiratory depression, including apnea. Unlike propofol, benzodiazepines used alone decrease blood pressure only modestly. Other drugs, particularly drugs that affect the cytochrome P-450 3A4 enzyme (including azole antifungals, human immunodeficiency virus [HIV] protease inhibitors, and calcium-channel blockers), affect the clearance of midazolam and prolong its half-life significantly. There are several reports of prolonged amnesia in HIV patients who received midazolam for conscious sedation. Midazolam also has an active metabolite and is often associated with delirium in elderly patients (Chapter 361), perhaps because it impairs both implicit and relational memory.

OPIOIDS

Opioids are classified as naturally occurring (morphine, codeine), semisynthetic (heroin), and synthetic (methadone, fentanyl, remifentanil). They can be administered both intravenously and in the neuraxial space (epidural or spinal). There are four opiate receptors (mu, kappa, delta, and nociceptin receptors), which are G protein–coupled receptors. Chronic exposure to agonists leads to cellular adaptation mechanisms that probably are involved in tolerance, dependence, and withdrawal. Clinically, mu agonists are used almost exclusively; mu agonists include morphine, fentanyl, and meperidine. Opioid analgesics are administered because they relieve pain, but they have other important effects, including respiratory depression, decreased gastric emptying, nausea and vomiting, sedation, constipation, pruritus, dependence, and tolerance, when given repeatedly. When opioids are given with propofol or benzodiazepines, there is a synergistic depressive effect on respiration, hence the rationale for monitoring patients who receive medications for conscious sedation. The rate of prolonged opioid use after surgery is approximately 3%, and characteristics associated with prolonged use include younger age, lower household income, diabetes, heart failure, and pulmonary disease. The recent focus on pain management as a marker of patient satisfaction and putative hospital quality may be one driver of the recent opioid crisis. For example, 70% of opioid-naïve patients who undergo low-risk surgical procedures fill a prescription for hydrocodone/acetaminophen or oxycodone/acetaminophen within 7 days after discharge or the procedure date. Physicians should be careful to avoid unnecessary opiate prescriptions and to limit prescriptions to several days. Such limitations of perioperative opioid prescriptions have become a priority for both health systems and state regulators.

KETAMINE

Ketamine is unique among the intravenous agents because it has analgesic properties and decreases tolerance to opiates. The metabolism of [RS]-ketamine to [2,6 R]-hydroxynorketamine [HNK] is necessary and sufficient to exert antidepressant actions in mice; its antidepressant effects are *N*-methyl-D-aspartate (NMDA) receptor–independent but involve early and sustained activation of α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptors. Ketamine produces dose-related analgesia, which may be profound even when patients can keep their eyes open, breathe spontaneously, and protect their own airway with conserved swallowing and cough reflex. Side effects include increased lacrimation, salivation, and muscle tone. Ketamine increases cerebral blood flow, can increase seizure activity, and can produce undesirable psychological reactions; these side effects are dose related and may be minimized by the concomitant use of benzodiazepines. Ketamine is also a bronchial smooth muscle relaxant and can prevent experimentally induced bronchospasm. Ketamine is usually associated with an increase in blood pressure, heart rate, and cardiac output. These features make ketamine a useful drug for sedating patients with hemodynamic instability and with depression. Intravenous ketamine under expert supervision also can provide significant short-term analgesic benefit in patients who have refractory chronic pain, but the optimal treatment protocol is not defined.

DEXMEDETOMIDINE

Dexmedetomidine is a highly selective α_2-agonist that is associated with less respiratory depression and more cooperative behavior than is propofol. Dexmedetomidine also causes hypnosis, analgesia, sympatholysis, and inhibition of insulin secretion. Dexmedetomidine induces sedation with a respiratory pattern and electroencephalographic changes similar to natural sleep. Even high concentrations of dexmedetomidine are associated with preservation of spontaneous respiration; however, when dexmedetomidine is administered in combination with sympatholytic or cholinergic agents, there is a high risk for extreme bradycardia and sinus arrest. Dexmedetomidine is associated with less amnesia than are benzodiazepines. Although propofol and benzodiazepines commonly have been used in critically ill patients to achieve sedation for procedures or for maintenance of mechanical ventilation, dexmedetomidine appears to have significant advantages over benzodiazepines because it can provide more comfort with a similar safety profile and decrease the time that critical care patients spend on ventilators. Dexmedetomidine also appears to help shorten the duration of perioperative delirium.[21]

VOLATILE ANESTHETICS

Volatile (inhalational) anesthetics include desflurane, sevoflurane, isoflurane, and nitrous oxide, as well as halothane, which now is rarely used in the United States. Inhaled anesthetics are absorbed through the respiratory epithelium and mucous membranes of the respiratory tract, and they are excreted mainly by exhalation. Access to the circulation is almost instantaneous, owing to the large pulmonary surface area. The pharmacologic effects of inhaled anesthetics depend primarily on alveolar ventilation, the ventilation-perfusion ratio, coadministered gases, gas flow, and the physicochemical properties of the anesthetic gas rather than on the quantity of drug administered, the extent and rate of absorption, protein binding, excretion, secretion, or metabolism.

All inhalational agents, with the exception of nitrous oxide, cause dose-dependent cardiovascular depression. Severe hepatotoxicity, which led to the discontinuation of the use of chloroform, carbon tetrachloride, and trichloroethylene anesthetics, is seen as fatal hepatic necrosis in 1 in 10,000 halothane anesthetics. This problem appears to occur much less frequently with isoflurane and desflurane. Mild halothane hepatoxicity is self-limited and can occur with a single exposure, whereas fulminant halothane hepatitis occurs only after multiple exposures to the drug, has a high mortality rate (50%), and is associated with antibodies to halothane-altered antigens. Volatile anesthetics, which are used in addition to or as a replacement for intravenous sedation in critically ill patients, may reduce the time to postoperative extubation.

Nitrous oxide, which is the only nonhalogenated agent still used, is not metabolized in human tissues. It irreversibly oxidizes the cobalt atom of vitamin B_{12}, thereby inhibiting the activity of the cobalamin-dependent enzyme methionine synthase. Individuals with vitamin B_{12} deficiency or with mutations of methionine synthase may be at risk for neurologic injury from nitrous oxide, which should not be used in patients at risk. Exposure to high concentrations of more than 10^3 ppm may be associated with an increased incidence of abortions and decreased fertility, so exposure should be avoided in patients and personnel at risk. Nitrous oxide is safe in major noncardiac surgery. General anesthesia can be achieved only by giving combinations of drugs along with nitrous oxide to achieve the desired effects. Based on the available evidence, no one general anesthetic appears to be superior to any other.

Volatile anesthetics are greenhouse gases, ozone-depleting agents, or both. As a result, the use of nitrous oxide and desflurane should be minimized if possible.[22]

NEUROMUSCULAR BLOCKERS

Neuromuscular blockers are used to paralyze muscles to facilitate endotracheal intubation and mechanical ventilation, to decrease shivering during induced hypothermia, or to improve conditions for optimal surgery. Succinylcholine

causes prolonged depolarization of the neuromuscular junction, thereby resulting in failure to generate an action potential. Within 9 to 13 minutes after 1 mg/kg of succinylcholine, 90% of muscle strength is restored. The very rapid onset and rapid return of muscle function make succinylcholine a useful drug for difficult intubations. Side effects of succinylcholine include hyperkalemia, myalgia, masseter spasm, sinus bradycardia and nodal rhythms, and increased intraocular pressure.

Most of the other neuromuscular drugs used by anesthesiologists are nondepolarizing in that they compete with acetylcholine for the neuromuscular junction and can be reversed by increasing the quantity of acetylcholine. These drugs are categorized by their chemical makeup: steroidal compounds, benzylisoquinolinium compounds, and other chemical compounds. Clinically, a drug is often chosen for its duration of action. Intermediate agents, which act for 20 to 50 minutes and are used most frequently, include vecuronium, rocuronium, atracurium, and cisatracurium. These drugs have different routes of metabolism, so the choice of agent depends in part on the presence of coexisting disease. The required dose of sugammadex to reverse the effects of neuromuscular blockade induced by rocuronium bromide and vecuronium bromide depends on the intensity of the neuromuscular blockade.[23]

The chronic administration of neuromuscular blocking agents is associated with prolonged paralysis, particularly in patients given concomitant steroids. Other notable interactions with nondepolarizing agents include that antibiotics can increase neuromuscular blockade; magnesium sulfate potentiates neuromuscular blockade; lithium can potentiate neuromuscular blockade with succinylcholine and with pipecuronium; antiepileptic drugs cause resistance to nondepolarizing muscle blockade so that larger doses must be administered to achieve paralysis; and patients receiving anticonvulsants have accelerated recovery from neuromuscular blockade.

Patients who have obstructive sleep apnea and who receive intraoperative neuromuscular blockers may be at higher risk for postoperative hypoxemia and respiratory failure. Reversal with sugammadex may reduce the risk of postoperative pulmonary complications.[24]

REGIONAL ANESTHESIA

Regional anesthesia involves the deposition of local anesthetics near nerves, including the deposition of local anesthetics in the epidural space and into the cerebrospinal fluid (CSF). Local anesthetics, which are aminoesters or aminoamides, affect cardiac function, as well as central nervous system function when administered systemically.

The binding of the local anesthetic to the sodium channels in the axoplasm prevents opening of the channels and conduction of nerve impulses. The rates of onset and recovery from nerve blockade are controlled by the diffusion of the local anesthetic into and out of the whole nerve.

Examples of regional anesthesia include neuraxial techniques, the deposition of local anesthetics near the brachial plexus to anesthetize the arms (axillary or intrascalene blocks), deposition near the femoral or sciatic nerves to anesthetize the legs, deposition near ulnar or radial nerves for lower arm blocks, deposition near the pudendal nerves for groin procedures, and deposition of local anesthesia in the caudal space for groin surgeries. Dentists employ this technique frequently when they inject local anesthesia near various nerves in the oral cavity. Many surgeries, including carotid surgery and the placement of fistulas for dialysis, can be performed with regional anesthesia. Regional anesthetics may also require supplementation with sedation or general anesthesia. Regional anesthesia can decrease postoperative pain and use of opioids.[25]

The dangers of regional anesthesia include the injection of local anesthesia into the systemic circulation. Systemic toxicity is manifested as convulsions and respiratory depression, which can require assisted ventilation. Tinnitus, visual and auditory disturbances, and dizziness are signs of milder central nervous toxicity. Cardiac toxicity can be manifested by decreases in heart rate, prolonged conduction times, and negative inotropic effects. Bupivacaine toxicity, which is associated with ventricular fibrillation, is more frequent in elderly patients. Treatment of local anesthetic systemic toxicity should include airway management, management of seizures, standard cardiovascular support, and lipid emulsion infusions.[26] Lower doses of epinephrine (<1 μg/kg) should be considered because the drug may interfere with the lipid resuscitation. Furthermore, the prolonged duration of many of the local anesthetics may require the institution of cardiopulmonary bypass until the drugs are metabolized.

NEURAXIAL (SPINAL AND EPIDURAL) ANESTHESIA AND ANALGESIA

Spinal anesthesia is the instillation of local anesthetics into the CSF. Epidural anesthesia is the instillation of larger volumes of local anesthetics into the epidural space, which is the potential space that exists just before the CSF. Spinal anesthesia is associated with an increased incidence of headache in younger patients, so epidural anesthesia is often used in younger patients. Complications of epidural and spinal anesthesia and analgesia include failed blocks, postdural puncture headaches, and toxicity from the local anesthetics. Another major concern of neuraxial anesthesia is that patients on antiplatelet agents may develop epidural hematomas, although epidural hematoma remains a rare event, occurring in fewer than 1 in 150,000 operations even in the presence of potent antiplatelet agents. Other, more rare complications of epidural and spinal anesthetics, in addition to the effects of local anesthesia outlined previously, include intracranial subdural hematoma, transverse myelitis, hypotension, and cardiac arrest.

Postoperative epidural analgesia, by which either local anesthesia or local anesthesia and narcotics are instilled into the epidural space for postoperative pain control, is associated with superior pain control, lower doses of opioids, improved bowel mobility, slightly decreased length of stay in the intensive care unit, and a slight decrease in the requirement for mechanical ventilation. The continuous intravenous infusion of perioperative lidocaine also may reduce pain and nausea, especially in the early postoperative period, but it is not as well studied as epidural anesthesia.[A8]

GENERAL VERSUS REGIONAL ANESTHESIA

Overall, there is no evidence that major postoperative cardiac events differ depending on whether non–cardiac surgery patients receive general, spinal, or epidural anesthesia.[A9,A10] When options are available, anesthesiologists and surgeons should offer patients the choice of less intensive anesthesia (i.e., spinal or epidural anesthesia or conscious sedation rather than general anesthesia, local anesthesia rather than conscious sedation), because such methods usually provide similar results.

However, the decision regarding what type of anesthesia should be administered often depends on the requirements of the surgery. For example, laparoscopic surgery requires general anesthesia because the insufflations of gases impair the ability to breathe adequately. General anesthesia is also required for surgeries on the airway or thorax because mechanical ventilation is usually needed to sustain adequate respiration. Procedures that do not allow any movement (e.g., precise procedures in the brain) often require general anesthesia and paralysis. For patients in whom the intraoperative technique could include general anesthesia, regional anesthesia, or a combination of the two, regional anesthesia may minimize pulmonary complications and modestly shorten hospital length of stay, but there currently is no evidence that it affects mortality.

Side effects of general anesthesia depend upon the drugs used to achieve anesthesia, whether neuromuscular blockade is administered, and whether mechanical ventilation is used. Complications of endotracheal intubation include local pain, trauma to the airway, swelling, vocal cord paralysis, increased bronchospasm, and death from improper placement. Volatile anesthetics are associated with postoperative atelectasis (Chapter 78), whereas regional anesthesia may help preserve respiratory dynamics. Postoperative cognitive dysfunction (Chapter 361) does not seem to depend on the type of anesthesia administered,[A11] but it may depend on the depth of accompanying sedation and severity of comorbid conditions.

NAUSEA AND VOMITING

Postoperative nausea and vomiting are more likely with volatile anesthetics but also are common when perioperative opioids are administered. Prophylactic ondansetron, dexamethasone, and droperidol each reduce postoperative nausea and vomiting, independently, by about 25%, with the main predictor for efficacy being the patient's risk for nausea and vomiting. It should be noted that droperidol has received a "black box" warning from the FDA, so it is not used very often in the United States. Total intravenous anesthesia with propofol reduces postoperative nausea and vomiting by only about 20%, often because narcotics are still administered. The use of spinal or epidural anesthesia may decrease the incidence of nausea and vomiting. In addition to general anesthesia, risk factors for postoperative nausea and vomiting include female gender, a prior history of nausea and vomiting, a history of motion sickness, nonsmoking, and intended administration of opioids for postoperative analgesia. If three or more risk factors are present, patients generally are recommended to receive at least two prophylactic pharmacologic antiemetic agents of different classes, selected among ondansetron (or ramosetron or granisetron), dexamethasone, or aprepitant preoperatively for the prevention of postoperative nausea and vomiting[A12] (Table 118-5).

401 POSTOPERATIVE CARE AND COMPLICATIONS

DONALD A. REDELMEIER

POSTOPERATIVE CARE

OVERVIEW

Postoperative medical complications are common, potentially fatal, and variable across different settings. Over 99% of perioperative deaths occur after the surgery, and nearly half are related to potentially treatable bleeding, myocardial injury, or systemic sepsis.[1] Large national studies show about a two-fold difference in risk for mortality between high- and low-ranked hospitals. However, analyses disagree about how much these differences reflect a greater incidence of each complication (failure of prevention around the time of surgery), a heightened lethality of each complication (failure to rescue in the aftermath of surgery), differences in the severity of disease (inherent differences among patients), and surgical skill (technical excellence). Regardless of the explanation, the purpose of medical consultation is to relieve human suffering by preventing, detecting, and correcting postoperative complications. The main constraint is that the consultant often has limited ongoing direct contact with the patient before or after the perioperative interval.

EFFECTIVE TEAMWORK

The medical consultant (Chapter 398) in the postoperative setting must have both a knowledge of medicine and an appreciation of the team psychology that can improve outcomes of patients. In contrast to other settings, the internist is not the team leader, often does not maintain an ongoing relationship with the patient, and does not have the authority of the most responsible physician. Moreover, patients may be dispersed across diverse surgical services, each with its own orientation and culture. The challenges of coordination and communication are enormous, particularly given the many other health care professionals involved in complex surgical cases. Considerable tact is often needed to avoid antagonizing the surgeon, disrupting the team's dynamics, or inducing a cascade of cumbersome inopportune testing. The development and use of safety checklists may be one effective way to enhance teamwork and to improve outcomes.

FOCUSING ON RECOVERY

Facilitating the patient's recovery from surgery differs from managing patients with acute exacerbations or chronic diseases. In the postoperative setting, many therapies must be stopped when the patient has recovered, such as discontinuing a urinary catheter because the patient can now void spontaneously or discontinuing a major tranquilizer because the patient is now oriented and coherent. Discontinuation of many other interventions requires substantial judgment, such as the decision when to discontinue intravenous access, supplemental oxygen, and intermittent laxatives. Much depends on experience and reconsideration of the individual patient's recovery on a regular basis.

READING ANESTHESIA RECORDS

A focused review of the anesthesia record is essential because the consultant is rarely present during the operation. Perhaps the most basic information to identify is the date of surgery because the time elapsed helps when interpreting the patient's current state of recovery. Sometimes the date is not immediately evident if more than one surgery has been performed, a planned operation was delayed, or some misquotations have arisen. Data about the duration of surgery, type of anesthesia (e.g., regional, spinal, or general [Chapter 400]), and major intraoperative events can help to establish reasonable expectations about the future course as well as the possibility of specific complications (e.g., epidural hematoma after spinal anesthesia). Sharing some of the basic data with the patient is often helpful because many individuals either benefit from repetition or are not otherwise informed.

PATTERNS OF MISTAKES

Medical errors (Chapter 10) that arise in postoperative care often seem mundane in retrospect, yet can be lethal if missed. Some patterns of mistakes have the feature of "double trouble," such as when a patient has both a potassium level of 2.0 mEq/L and lithium level of 2.0 mEq/L, but care focuses on only one of these two metabolic abnormalities. Other mistakes occur because a problem arises at an awkward moment, such as when one patient develops acute dyspnea at the same time when another patient is having a seizure. Still other mistakes relate to the fallibility of human memory and attention, such as when a normal blood glucose value in the morning leads clinicians to presume that the level is still normal at night. These errors can result in substantial harm, failures of clinicians to learn from past mistakes, and unprofessional reactions related to lingering embarrassment. None of these patterns are unique to postoperative care, yet the fast and unfamiliar terrain of surgical settings can make even simple mistakes difficult to avoid.

CHECKING ORDERS

The first method for reducing errors after surgery is to check the postoperative orders already written for the patient. Such double-checking is a tedious task, and clinicians often direct insufficient attention to this review in the faulty belief that most of the work is already done. Ironically, checking orders written by another clinician requires more than customary attention because of the challenges of following someone else's legibility, sequencing, and preferences. The set of orders may need to be read twice: once for errors of commission (e.g., a calcium-channel blocker ordered at the wrong dose) and once for errors of omission (e.g., a β-blocker inadvertently not reordered after surgery). One classic mistake on postoperative orders is failure to follow through on interventions initiated immediately before surgery (e.g., delirium tremens prophylaxis). A particularly vexing issue is the need for repeated rechecking on subsequent days (e.g., new orders for unnecessary sedative medications).

RECOMMENDED PROPHYLAXIS

Some complications are sufficiently frequent and serious that routine prophylaxis is justified in the postoperative setting. For example, systemic anticoagulation is indicated for patients at risk for postoperative deep venous thrombosis (Chapters 68 and 70). Gastric acid suppression (Chapter 125) is justified for patients at high risk for postoperative gastric bleeding. Laxatives are indicated for patients who are receiving systemic opioids. In contrast, antibiotic prophylaxis is indicated only for selected patients who are at high risk for endocarditis (Chapter 61), and antibiotic prophylaxis to prevent surgical site infections can be discontinued immediately if best practice standards are followed.[A1]

401 POSTOPERATIVE CARE AND COMPLICATIONS

DONALD A. REDELMEIER

POSTOPERATIVE CARE

OVERVIEW

Postoperative medical complications are common, potentially fatal, and variable across different settings. Over 99% of perioperative deaths occur after the surgery, and nearly half are related to potentially treatable bleeding, myocardial injury, or systemic sepsis.[1] Large national studies show about a two-fold difference in risk for mortality between high- and low-ranked hospitals. However, analyses disagree about how much these differences reflect a greater incidence of each complication (failure of prevention around the time of surgery), a heightened lethality of each complication (failure to rescue in the aftermath of surgery), differences in the severity of disease (inherent differences among patients), and surgical skill (technical excellence). Regardless of the explanation, the purpose of medical consultation is to relieve human suffering by preventing, detecting, and correcting postoperative complications. The main constraint is that the consultant often has limited ongoing direct contact with the patient before or after the perioperative interval.

EFFECTIVE TEAMWORK

The medical consultant (Chapter 398) in the postoperative setting must have both a knowledge of medicine and an appreciation of the team psychology that can improve outcomes of patients. In contrast to other settings, the internist is not the team leader, often does not maintain an ongoing relationship with the patient, and does not have the authority of the most responsible physician. Moreover, patients may be dispersed across diverse surgical services, each with its own orientation and culture. The challenges of coordination and communication are enormous, particularly given the many other health care professionals involved in complex surgical cases. Considerable tact is often needed to avoid antagonizing the surgeon, disrupting the team's dynamics, or inducing a cascade of cumbersome inopportune testing. The development and use of safety checklists may be one effective way to enhance teamwork and to improve outcomes.

FOCUSING ON RECOVERY

Facilitating the patient's recovery from surgery differs from managing patients with acute exacerbations or chronic diseases. In the postoperative setting, many therapies must be stopped when the patient has recovered, such as discontinuing a urinary catheter because the patient can now void spontaneously or discontinuing a major tranquilizer because the patient is now oriented and coherent. Discontinuation of many other interventions requires substantial judgment, such as the decision when to discontinue intravenous access, supplemental oxygen, and intermittent laxatives. Much depends on experience and reconsideration of the individual patient's recovery on a regular basis.

READING ANESTHESIA RECORDS

A focused review of the anesthesia record is essential because the consultant is rarely present during the operation. Perhaps the most basic information to identify is the date of surgery because the time elapsed helps when interpreting the patient's current state of recovery. Sometimes the date is not immediately evident if more than one surgery has been performed, a planned operation was delayed, or some misquotations have arisen. Data about the duration of surgery, type of anesthesia (e.g., regional, spinal, or general [Chapter 400]), and major intraoperative events can help to establish reasonable expectations about the future course as well as the possibility of specific complications (e.g., epidural hematoma after spinal anesthesia). Sharing some of the basic data with the patient is often helpful because many individuals either benefit from repetition or are not otherwise informed.

PATTERNS OF MISTAKES

Medical errors (Chapter 10) that arise in postoperative care often seem mundane in retrospect, yet can be lethal if missed. Some patterns of mistakes have the feature of "double trouble," such as when a patient has both a potassium level of 2.0 mEq/L and lithium level of 2.0 mEq/L, but care focuses on only one of these two metabolic abnormalities. Other mistakes occur because a problem arises at an awkward moment, such as when one patient develops acute dyspnea at the same time when another patient is having a seizure. Still other mistakes relate to the fallibility of human memory and attention, such as when a normal blood glucose value in the morning leads clinicians to presume that the level is still normal at night. These errors can result in substantial harm, failures of clinicians to learn from past mistakes, and unprofessional reactions related to lingering embarrassment. None of these patterns are unique to postoperative care, yet the fast and unfamiliar terrain of surgical settings can make even simple mistakes difficult to avoid.

CHECKING ORDERS

The first method for reducing errors after surgery is to check the postoperative orders already written for the patient. Such double-checking is a tedious task, and clinicians often direct insufficient attention to this review in the faulty belief that most of the work is already done. Ironically, checking orders written by another clinician requires more than customary attention because of the challenges of following someone else's legibility, sequencing, and preferences. The set of orders may need to be read twice: once for errors of commission (e.g., a calcium-channel blocker ordered at the wrong dose) and once for errors of omission (e.g., a β-blocker inadvertently not reordered after surgery). One classic mistake on postoperative orders is failure to follow through on interventions initiated immediately before surgery (e.g., delirium tremens prophylaxis). A particularly vexing issue is the need for repeated rechecking on subsequent days (e.g., new orders for unnecessary sedative medications).

RECOMMENDED PROPHYLAXIS

Some complications are sufficiently frequent and serious that routine prophylaxis is justified in the postoperative setting. For example, systemic anticoagulation is indicated for patients at risk for postoperative deep venous thrombosis (Chapters 68 and 70). Gastric acid suppression (Chapter 125) is justified for patients at high risk for postoperative gastric bleeding. Laxatives are indicated for patients who are receiving systemic opioids. In contrast, antibiotic prophylaxis is indicated only for selected patients who are at high risk for endocarditis (Chapter 61), and antibiotic prophylaxis to prevent surgical site infections can be discontinued immediately if best practice standards are followed.[A1]

ABSTRACT

Postoperative care requires identifying and correcting medical complications in complex surgical patients. This chapter reviews the fundamentals of effective teamwork, interpretation of common patient symptoms, treatment of other abnormal signs or laboratory abnormalities, and selected nuances related to special situations. The goal of medical consultation is to relieve suffering by the prevention, detection, and treatment of postoperative complications.

KEYWORDS

postoperative complications
general internal medicine
medical consultation
surgical complications
shared patient management

The optimal method for gauging whether a patient is at high risk for each complication is contentious and thereby leads to variation in practice patterns across different settings.

FUTURE PREVENTION

A postoperative consultant who maintains communication, facilitates the patient's recovery, and avoids postoperative mistakes also has the chance to initiate medical interventions for general medical care. Such opportunities for prevention might include influenza vaccination, colon cancer screening, and cholesterol reduction. The main advantage of such comprehensive care is that it conforms to the ideal of providing all services possible to the individual. The main disadvantage of such comprehensive care is the potential for creating commotion, confusion, or misquotation (Chapter 398). Such unintended consequences distract the surgical team and also carry some risk for side effects at a time when the patient is trying to recover from surgery. Many effective postoperative consultants will defer such opportunities for prevention to the outpatient physicians who assume long-term responsibility for the patient's care.

COMPLICATIONS

SYMPTOMS

Chest Pain

Chest pain is a common problem after surgery and has an extensive differential diagnosis (Chapter 39). In the postoperative setting, the immediate consideration is an acute ischemic myocardial event. The diagnosis of a perioperative myocardial infarction (MI) differs somewhat from community-acquired MI (Table 401-1). Interpretation of a patient's symptoms, examination findings, and electrocardiogram is often problematic because of changes related to surgery and anesthesia. In particular, diagnosis is heavily dependent on biomarkers, such as an elevated troponin level, especially because many postoperative MIs are painless.

Management priorities include supplemental oxygen, heart rate control, and correction of severe anemia. Thrombolysis is often contraindicated, but percutaneous coronary intervention may be considered, especially because of the high 30-day mortality rate for postoperative MI, although data on its benefits are lacking. Dabigatran (110 mg twice daily) can reduce the risk of major vascular complications without increasing major bleeding in patients who develop evidence of myocardial injury after noncardiac surgery.[A2] Otherwise, therapies such as aspirin, clopidogrel, nitrates, statins, and angiotensin-converting enzyme inhibitors, should be considered on a case-by-case basis (Chapter 58).

Dyspnea

Shortness of breath (Chapter 71) after surgery has an extensive differential diagnosis (Table 401-2). The three key considerations are fluid overload from heart failure (Chapter 45), pulmonary embolism (Chapter 68), and air space disease (a continuum encompassing atelectasis [Chapter 78], bronchitis [Chapter 84], aspiration [Chapter 82], mucous plugging, and pneumonia). Distinguishing among these considerations requires focusing on the speed of onset, timing relative to surgery, vital sign abnormalities, findings on oximetry, and physical examination (Chapter 71). The evaluation should focus on a review of background comorbid conditions, an electrocardiogram, and a chest radiograph to assess for cardiac and pulmonary causes. Fluid overload is most commonly seen soon after the cessation of positive-pressure ventilation or vasodilating analgesia. It is also common 3 to 5 days postoperatively when fluid that had been extravasated into interstitial tissue is shifted back into the intravascular compartment. The results of the initial evaluation can guide further efforts to diagnose or confirm causes such as myocardial ischemia (Chapters 57 and 58), arrhythmias (Chapters 51 to 53), atelectasis (Chapter 78), pneumonia (Chapter 85), and venous thromboembolic disease (Chapter 68).

When no serious underlying cause is found, interventions that are safe in most situations include administration of oxygen and withholding of sedation. The use of noninvasive ventilation can reduce the rate of reintubation in hypoxemic postoperative patients compared with the use of oxygen alone.[A3] Other interventions that will be helpful or harmful, depending on the situation, include diuretics, opioids, and vigorous physiotherapy. Despite its common use, incentive spirometry is of little benefit.[A4]

TABLE 401-1 CRITERIA FOR DIAGNOSIS OF POSTOPERATIVE MYOCARDIAL INFARCTION

The diagnosis of perioperative MI requires any one of the following criteria.
Criterion 1: A typical rise in the troponin level or a typical fall in an elevated troponin level detected at its peak after surgery in a patient without a documented alternative explanation for an elevated troponin level (e.g., pulmonary embolism). This criterion requires that one of the following criteria be met: Ischemic signs or symptoms (e.g., chest, arm, or jaw discomfort; shortness of breath; pulmonary edema) Development of pathologic Q waves on an ECG Changes on an ECG indicative of ischemia Coronary artery intervention New or presumed new cardiac wall motion abnormality on echocardiography or new or presumed new fixed defect on radionuclide imaging
Criterion 2: Pathologic findings of acute or healing MI
Criterion 3: Development of new pathologic Q waves on an ECG if troponin levels were not obtained or were obtained at times that could have missed the clinical event

ECG = electrocardiogram; MI = myocardial infarction.

Adapted from Devereaux PJ, Goldman L, Yusuf S, et al. Surveillance and prevention of major perioperative ischemic cardiac events in patients undergoing noncardiac surgery: a review. *CMAJ*. 2005;173:779-788.

Anorexia

Loss of appetite (Chapter 118) after surgery has an extensive differential diagnosis that can be narrowed substantially if the patient was eating properly before surgery. The immediate priority is to search for and correct underlying contributors. Enteral or parenteral support is not the priority initially, although such support may eventually become indicated. Drug toxicity is a particularly common and rapidly reversible contributor to postoperative anorexia. Anatomic abnormalities are usually evident by medical imaging studies. Common metabolic contributors include abnormalities in potassium, bicarbonate, calcium, phosphorus, and magnesium. Acalculous cholecystitis (Chapter 141) is an important postoperative complication that must be considered in a patient with right upper quadrant tenderness. Constipation is another frequent contributor that often responds to increased laxatives.

Vomiting

Vomiting is the extreme form of nausea in the postoperative setting, and the two symptoms share the same differential diagnosis. In most patients, vomiting is unexpected and merits immediate attention. Initial management is to ensure that the patient's airway is protected, discontinue oral medications (and find parenteral substitutes if necessary), and consider insertion of a nasogastric tube. In patients after gastrointestinal surgery, the priority considerations include the possibility of an anastomotic leak, peritoneal abscess, or another anatomic abnormality. In patients after operations on more remote parts of the body, the priority considerations are emetogenic medications (such as postoperative chemotherapy), gastroparesis associated with autonomic neuropathy, and fecal impaction. Multiple antinausea medications are available for symptomatic relief (e.g., aprepitant, ramosetron, granisetron, prochlorperazine, ondansetron, and dexamethasone [which can be given safely without increasing the risk of surgical site infection[A5]], and droperidol; see Table 118-5)[A6] and act in an additive manner when they are used in combination (e.g., prochlorperazine 5 mg intramuscularly plus ondansetron 4 mg intramuscularly). If no reversible contributor is identified, the default diagnosis is prolonged idiopathic ileus, and a therapeutic trial of intravenous neostigmine can be considered (e.g., neostigmine 2.5 mg intravenously over 5 minutes).

Diarrhea

Diarrhea (Chapter 126) is rare after surgery and involves a limited number of possibilities if the patient's bowel movements were normal before surgery. In such cases, the situation represents an acute-onset diarrhea that is usually secretory in nature. An immediate priority is to exclude toxic megacolon, which is a potential emergency caused by overgrowth of toxigenic *Clostridioides difficile* (Chapter 271). Clinical evaluation for toxic megacolon requires assessment for tachycardia, hypotension, delirium, and other signs of sepsis rather than waiting on initial stool studies for confirmation of infection with *C. difficile*. Risk factors for antibiotic-associated diarrhea include advanced age, use of broad-spectrum antibiotics (e.g., third-generation cephalosporins), and unknown host susceptibility factors (e.g., past episodes of pseudomembranous colitis). A definitive diagnosis is frequently never established, and treatment focuses on feeding the patient a lactose-free diet while avoiding intestinal paralytics.

TABLE 401-2 DISTINGUISHING AMONG COMMON CAUSES OF ACUTE POSTOPERATIVE DYSPNEA

	PULMONARY AIR SPACE	FLUID OVERLOAD/HEART FAILURE	PULMONARY THROMBOEMBOLISM
CHARACTERISTICS OF TIMING			
Days since surgery	1-7 days	0-5 days	5-28 days
Speed of onset	1-3 days	1-24 hours	1-5 minutes
PREVIOUS HISTORY			
Previous lung disease	++		
Previous heart failure		++	
Previous venous thrombosis			++
ABNORMAL VITAL SIGNS			
Temperature	+		
Heart rate	+	+	+
Blood pressure	+	+	++
Respiratory rate	+	++	+
Oximetry	++	+	+
PHYSICAL EXAMINATION			
Jugular venous distention		+	+
Pulmonary rales	+	++	
S_3 gallop		++	
RESPONSE TO TREATMENT			
Oxygen	+	+	+
Anticholinergic bronchodilators	+	+	+
Withdrawal of sedatives	+	+	+
Aggressive physiotherapy	++		
Diuretics/afterload reduction		++	

Complete resolution is typical provided that adequate fluid and electrolyte levels are maintained.

Weakness

Generalized weakness after surgery is almost inevitable, but focal weakness may sometimes reflect nerve damage caused by intraoperative positioning (e.g., damage to the facial nerve after carotid endarterectomy) and only rarely indicates a new intracranial event (e.g., intracerebral bleeding [Chapter 377] due to anticoagulation). Focal neurologic deficits are often overlooked during the initial postoperative interval and may become apparent only after the patient has regained strength elsewhere in the body. Conversely, new deficits that are evident early after surgery and resolve rapidly thereafter may reflect unmasking of an old stroke that was fully compensated during less stressful circumstances. Medical imaging of the brain is worthwhile if no explanation is apparent on initial assessment. Diffuse neurologic weakness is usually due to deconditioning and commonly responds to physical therapy.

Delirium

Changes in mental status after surgery are common, especially in elderly patients (Chapter 361), and can be remarkably prolonged.[2] The immediate priorities are to determine whether the impairment is acute or chronic and to detect easily reversible contributors (such as infection, hypoglycemia, and alkalosis). An exhaustive assessment is often unnecessary if the patient had normal mental status before surgery because many dementia syndromes are thereby excluded (such as vitamin B_{12} deficiency, tertiary syphilis, or Alzheimer disease). Multicomponent interactions that can help prevent delirium in hospitalized patients[3] include discontinuation of medications (e.g., anticholinergics, opioids, and tranquilizers) and the continuous presence of friends or family members who can provide frequent orientation and constant attention.[A7] In one randomized trial, intravenous dexmedetomidine (0.1 µg/kg per hour, from intensive care unit admission on the day of surgery until 8 AM on postoperative day 1) decreased the occurrence of delirium by about two thirds during the first 7 days after noncardiac surgery,[A8] but it has not shown efficacy in other studies.[A9] Data on melatonin and ramelteon for the prevention of delirium are also mixed (Chapter 361).

Once delirium develops, a sense of patience is necessary because normalization rarely occurs instantly. Low-dose neuroleptics (e.g., risperidone, 0.5 mg by mouth twice daily) or haloperidol (0.25 to 0.5 mg intramuscularly, repeated up to every 30 minutes and no more than 3 to 5 mg over 24 hours) can be used to achieve sedation (Chapter 361). However, antipsychotic medications are generally unhelpful and may prolong the course of delirium.[A10] Delirium after surgery is associated with a significant decline in cognitive ability during the next year, with a trajectory characterized by an initial decline and prolonged impairment.

Seizures

The development of uncontrolled seizures (Chapter 372) after surgery is rare. The immediate priorities are to exclude status epilepticus, to uncover any history of seizures, and to identify provocative factors. Neurosurgical patients typically undergo a standardized treatment protocol, including steroids and anticonvulsants. Other conditions that can cause abnormal motor movements must be excluded, such as septic rigors, delirium tremens, Parkinson disease, major psychopathology, hypothermic shivering, and hypercapnic asterixis. Additional priorities include the detection and correction of underlying metabolic abnormalities such as hypocalcemia, hypoxemia, hyponatremia, hypophosphatemia, and drug toxicity. Treatment focuses primarily on reversing the underlying precipitating cause and providing nonspecific care with benzodiazepines, phenytoin, and ongoing monitoring.

SIGNS

Hypertension

Hypertension may reflect a variety of disorders and must be treated in a manner that neither overreacts nor underreacts to the situation. Hypertension is particularly common after neurosurgical procedures or carotid endarterectomy. The initial assessment focuses on whether the patient has chronic hypertension based on the past history, current electrocardiogram, or findings on fundoscopy. Other potential causes include undertreated pain, agitated delirium, fluid overload, alcohol withdrawal, and inadvertent discontinuation of chronic antihypertensive medications. In uncertain cases, systemic analgesia is often helpful, along with nitrates (e.g., nitroglycerin, 0.4 mg/hr transdermally) and β-blockers (e.g., metoprolol, 5 mg intravenously). The major complication of treatment is the potential for overcorrection and inadvertent hypotension; such errors are particularly common in patients with no evidence of past hypertension.

Hypotension

Hypotension (Chapter 7) after surgery is generally an emergency, and the immediate concern is internal bleeding, especially after intra-abdominal operations or when anticoagulation is initiated to prevent thrombosis. The early stages of hypotension are frequently unrecognized because of autonomic stress responses by patients, psychological denial by clinicians, and misattribution to the concurrent use of analgesia. Early hypotension is particularly easy to overlook if the patient has coexisting chronic hypertension and the apparently "normal" blood pressure is dismissed as unremarkable. Prompt echocardiography can almost always find the cause of undiagnosed hemodynamic instability. Treatment usually entails volume supplementation, vasopressors as needed (Chapters 93 and 94), serial assessments, and a search for underlying causes. An extensive differential diagnosis sometimes needs to be considered if no anatomic cause related to surgery is evident (Chapter 92). Routine use of pulmonary artery catheters to guide therapy is not helpful, and goal-directed fluid therapy does not reduce mortality beyond standard fluid resuscitation.[A11]

Hypoxemia

Postoperative hypoxemia is common after noncardiac surgery, with about 20% of patients having oxygen saturations below 90% averaged over the first 48 hours and about one third of patients having oxygen saturations below 90% for an hour or more. Many of these events are not clinically diagnosed but can be detected by continuous monitoring. The clinical implications of undiagnosed hypoxemia are uncertain, but they may contribute to anorexia, delirium, and cardiac sequelae. The evaluation is similar to the evaluation of dyspnea (see earlier). Treatment generally requires supplemental oxygen, encouragement of deep breathing, and specific treatment aimed at any underlying causes.[4] Inhaled bronchodilators have not been proven effective unless the patient has a clear history of reactive airway disease.

Tachycardia

Tachycardia after surgery can be caused by myriad arrhythmias (Chapters 52 and 53) and may contribute to postoperative cardiac ischemia. Distinguishing between newly detected and newly incident tachycardia can sometimes be accomplished by determining whether the patient does or does not complain of palpitations. An initial assessment also requires review of the electrocardiogram to distinguish atrial fibrillation from other disorders. The goal of treatment is to identify and correct precipitating factors such as pain, blood loss, hypoxia, electrolyte abnormalities, fluid overload, volume depletion, pulmonary embolism, and drug withdrawal. Most arrhythmias respond to correction of the underlying abnormality. Specific antiarrhythmic treatment, when needed, is generally similar to that used in the nonoperative setting (Chapters 52 and 53). For atrial fibrillation, anticoagulation is sometimes contraindicated; in such situations, cardioversion within 48 hours merits consideration. Postoperative atrial fibrillation portends an increased long-term risk of ischemic stroke.[5]

Fever

Fever (Chapter 259) after surgery is common,[6] frequently perplexing, and often multifactorial. Worrisome possibilities include transfusion reactions (Chapter 162), hospital-acquired pneumonia (Chapter 85), urinary tract infection (Chapter 263), line sepsis (Chapter 261), and surgical site infection. In many cases, no definitive cause is found, the patient recovers spontaneously, and the default diagnosis is atelectasis. Detailed evaluation, when necessary, requires cultures of blood, urine, and the surgical site to identify specific microbiologic organisms. Selection of empirical antibiotics is usually based on local practice patterns and hospital ecology, with the disadvantage of breeding resistant organisms. Hydration, nutrition, and general supportive care are important yet frequently neglected issues for patients with prolonged elevations in body temperature. Selective decontamination of the digestive tract and oropharynx appears to be beneficial, but chlorhexidine is not (Chapter 261).

Edema

Peripheral edema (Chapter 39), which is often first noticed by nursing staff after surgery, is rarely life threatening unless it is treated with excessive diuretics. The cause is usually multifactorial and includes increased hydrostatic pressure (including heart failure and gravity from intraoperative positioning), decreased oncotic pressure (related to hypoalbuminemia from decreased liver production or increased losses), and accentuated capillary leak (potentially caused by medications or tissue reactions). Treatment focuses on correction of underlying abnormalities, maintenance of nutrition, judicious use of diuretics, monitoring renal function, provision of systemic anticoagulation against deep venous thrombosis, and efforts toward mobilization of the patient. A low-salt diet, afterload reduction, and aldosterone antagonists (e.g., oral spironolactone, 25 mg once daily) may be helpful in patients in whom heart failure (Chapter 46) is the dominant mechanism.

LABORATORY

Leukocytosis

An elevated white blood cell count (Chapter 153) can have many causes, but the immediate priority is to exclude a life-threatening septic process (Chapters 92 and 94). Direct microscopic examination of the peripheral blood smear (Chapter 143) can be helpful to check for toxic granulations (see Fig. 143-18), Döhle bodies (see Fig. 143-19), and a shift toward primitive band cells. Many cases are due to noninfectious causes, including infarcted tissue (skin, heart, intestinal tract), inflammatory conditions (renal insufficiency, diabetic ketoacidosis, lupus erythematosus), and demargination stress reactions (dehydration, systemic corticosteroids, inotropic medications). In the absence of direct evidence, some clinicians may initiate antibiotics empirically, whereas others may elect waiting. Substantial controversy remains about the proper duration of an empirical trial of antibiotics when no cause is discovered and the patient is otherwise recovering.

Anemia

Anemia (Chapter 144) is common and sometimes underappreciated because coexisting volume depletion causes the blood hemoglobin concentration to underestimate the degree of blood loss. Major perioperative hemorrhage is associated with subsequent stroke, myocardial injury, and all-cause nonfatality[7] in patients undergoing noncardiac, non-neurologic surgery. The initial priority is to differentiate bleeding at the surgical site from other causes. In many cases, the exact cause is unclear and substantial uncertainty may arise over the need to initiate gastric acid suppression therapy or to interrupt systemic anticoagulation against venous thrombosis. In a large randomized trial, transfusion at a hemoglobin threshold of 10 g/dL was no better than transfusion for symptoms of anemia or at the physician's discretion for a hemoglobin level of below 8 g/dL.[8] Guidelines for transfusion therapy depend on the patient's cardiac reserve, hemodynamic stability, evidence of active postoperative bleeding, and the available blood bank supply at the particular medical center. A reasonable goal is to maintain a hemoglobin level of 7 to 9 mg/dL in patients who are hemodynamically stable, except in patients with cardiovascular disease or after orthopedic surgery, in whom a hemoglobin goal of 8 mg/dL is reasonable.[A12,A13] Other exceptional situations include patients with hemodynamic instability, ongoing myocardial ischemia, severe thrombocytopenia, or chronic transfusion-dependent anemia, in whom the threshold of 9 mg/dL is reasonable (Chapter 162).[9] The immediate postoperative interval is not usually the appropriate time to initiate erythropoietin, oral iron replacement, or detailed evaluations for other hematologic abnormalities.

Abnormalities in Platelet Count

Patients often have abnormal platelet counts after surgery yet rarely require further evaluation or treatment.[10] In most cases, the thrombocytopenia is mild, does not require transfusion therapy, resolves in a few weeks, and is not a sign of an ominous disorder (e.g., sepsis or heparin-induced thrombocytopenia). Platelet transfusions are indicated if the decrease in platelet count is extreme, accompanied by evidence of major blood loss, or related to recent surgery on the central nervous system (including the eye). Thrombocytosis is also common after surgery and is occasionally extreme. However, even postoperative thrombocytosis exceeding 1,000,000/mL rarely necessitates treatment, does not predispose patients to unwanted clotting complications, and typically resolves spontaneously after a few weeks.

Abnormal Sodium Concentration

Both hyponatremia and hypernatremia (Chapter 102) are frequent complications in the postoperative setting. The immediate priorities are to assess the patient's intravascular volume status and to correct possible volume depletion. The causes of hyponatremia are multifactorial, including excessive use of diuretics, high levels of intrinsic antidiuretic hormone (as a result of factors such as drugs, pain, mechanical ventilation), and unmeasured osmoles (e.g., intravenous contrast agents). The risk for postoperative hyponatremia may be reduced by the administration of isotonic saline rather than by water restriction. Once hyponatremia develops, vasopressin antagonists (Chapter 102) can be effective for both hypervolemic and euvolemic hyponatremia. Hypernatremia is always

due to free water deficiency, which may indicate severe cognitive impairment or other factors interfering with the ability to express thirst or to ingest water. Correction is similar to that in the nonoperative setting. Abnormalities in sodium concentration require careful follow-up, can recur at any point after an operation, yet are rarely the root cause of a patient's inability to recover from surgery.

Abnormal Serum Potassium Concentration

Hyperkalemia and hypokalemia (Chapter 103) are also frequent postoperative complications. The immediate priority is to assess the patient's electrocardiogram and to stabilize the patient's electrocardiophysiology. Hyperkalemia is usually due to cellular shifts, renal failure, and tissue destruction (including hemolysis). Hyperkalemia will generally be corrected with treatments that shift potassium into cells (e.g., intravenous glucose with or without insulin) and enhance total excretion (e.g., gastrointestinal binding agents). Hypokalemia is usually due to inadequate intake, excessive loss, or cellular shifts. Hypokalemia will generally be corrected with replacement therapy and rarely requires aldosterone antagonism. Both abnormalities can usually be treated as in the nonoperative setting (Chapter 103). The prognosis is favorable if the patient's electrocardiogram shows no major dysrhythmias and if renal function is preserved.

Alkalosis

Systemic alkalosis (Chapter 104) typically requires volume supplementation because the cause is generally intravascular volume depletion. Blood gas determinations may be necessary in some cases to exclude the possibility of concurrent carbon dioxide retention with compensatory metabolic alkalosis. Untreated, alkalosis can result in altered mentation, cardiac arrhythmias, and delayed mobilization. Most patients with postoperative alkalosis do not require carbonic anhydrase inhibitors or intravenous acid. The prognosis is usually favorable, with gradual correction during a period of several days. Rapid correction of alkalosis, unlike rapid correction of hyponatremia, is not known to cause neurologic injury.

Azotemia

The initial assessment of an elevated serum creatinine concentration (Chapter 100) focuses on reviewing previous values (to distinguish acute from chronic renal insufficiency) and identifying contributing factors (such as prerenal volume depletion, intrarenal nephrotoxins, or postrenal urethral obstruction). A trial of intravenous fluids may be useful on both a diagnostic and therapeutic basis. Treatment is the same as in the nonoperative setting. Subsequent monitoring is usually necessary, with serum creatinine measurements obtained on a once-daily basis. Serial measurements of urinary volume and body weight as well as a urine culture are occasionally helpful in selected cases. Postoperative acute kidney injury is strongly associated with poorer long-term outcomes.[11]

Hyperbilirubinemia

Elevations in serum bilirubin (Chapter 133) are rare after surgery, even though abnormalities in liver enzyme levels occur frequently with general anesthesia. The most benign explanation is Gilbert syndrome, but the immediate priority is to assess for possible hepatic failure (especially in patients who have received volatile agents). As in the nonoperative setting, treatment involves withdrawing potential hepatotoxins, supporting the patient, and allowing time for liver function to recover (Chapter 139). Treatment of hepatic encephalopathy is particularly important because of the concurrent constipation and generalized catabolic state that follow major surgery. Monitoring should include serial measurement of liver function on a daily basis because each component (e.g., bilirubin, albumin, prothrombin time) can be altered by factors unrelated to the liver. The prognosis is unfavorable if the patient's liver function fails to recover quickly.

Hypoalbuminemia

Reductions in serum albumin are common after surgery and are an ominous prognostic finding. The cause is rarely decreased production if the reduction in the albumin level occurs rapidly. Possible explanations include nephrotic syndrome, capillary leak into extravascular spaces, and occult catabolism in unrecognized sites. Treatment with albumin infusions does not usually normalize the metabolic abnormality and does not seem to improve patient survival. The main priorities are to continue nutritional support, preserve skin integrity, minimize the use of systemic diuretics, correct any contributing factors, and consider correlated serum protein deficiencies (such as reduced levels of immunoglobulins or antithrombin III). Hypoalbuminemia can also cause substantial indirect harm by the loss of carrier proteins, which thereby predisposes patients to potential drug toxicity. The long-term prognosis is favorable for survivors because the serum albumin level will eventually return to normal.

Abnormalities in Blood Glucose Concentration

In patients with diabetes mellitus (Chapter 210), serum blood glucose concentrations often become unstable after surgery because of altered dietary intake, decreased physical activity, and the release of counter-regulatory hormones. The priority is to avoid hypoglycemia, severe hyperglycemia, diabetic ketoacidosis, cerebral damage, and repeated events. Intensive control of the blood glucose level increases the risk for severe hypoglycemia and death, so a target glucose level of about 140 to 200 mg/dL is recommended. Rapid reversal of sepsis or focal infection can lead to a precipitous decrease in insulin requirements; in such cases, vigilance is required because unsuspected hypoglycemia may cause permanent damage or be fatal in a patient who may otherwise seem to be sleeping. Patients need to be forewarned that temporary doses of subcutaneous insulin may be required but do not commit the patient to chronic insulin therapy. Monitoring involves serial measurement of blood glucose concentration until the patient is eating in a reliable manner.

Troponin and Natriuretic Peptide Levels

Among patients undergoing noncardiac surgery, the peak postoperative troponin level during the first 3 days after surgery is significantly associated with 30-day mortality, even if patients do not have any other evidence of an acute MI.[12,13] The potential utility of routine postoperative troponin levels for patient management remains uncertain, but data support routine postoperative screening with a daily troponin level in patients who are over age 60 years and who underwent emergent surgery and in patients who underwent elective surgery with a Revised Cardiac Risk Index score (Table 399-4) of 3 or more.[14] The detection of an elevated troponin level should prompt a careful search for symptoms or signs of myocardial ischemia and trigger the use of a statin and, if associated with ischemic electrocardiographic changes, consideration of low-dose aspirin (81 mg daily) and perhaps dabigatran (110 mg twice daily; see Chest Pain, earlier).[15] Similarly, screening and monitoring levels of brain natriuretic peptides is favored in some guidelines and not in others.

SPECIAL SITUATIONS

Multiplicity

Some postoperative complications are difficult to classify because no single dominant problem is apparent by symptoms, signs, or laboratory test results. Instead, patients may have multiple problems that need to be addressed simultaneously. The immediate goal is to set priorities and to avoid the temptation to try to eliminate every possibility on the first day. The corollary is to continue to check progress during the subsequent days needed for a complete diagnosis and successful therapy. Because so many concerns require attention in the postoperative interval, the risk is that clinicians will lose track of a secondary issue and make an error that seems obvious in retrospect.

Redundancy

Postoperative complications sometimes generate multiple consultations with physicians who have overlapping abilities. An example might be a patient with a postoperative fever who prompts consultations from pulmonology, dermatology, general medicine, and infectious disease specialists. In theory, gathering a critical mass of medical experts together should increase the likelihood of accurate diagnosis, timely treatment, and foolproof follow-up. In reality, however, coordination and communication are never perfect. Personal rivalries, diffusion of responsibility, and many other psychological factors may impede interactions among consultants. Opportunities for miscommunication may be further accentuated if the patient has an exotic diagnosis that is a special draw on the consultant's attention (e.g., pheochromocytoma). Arguing in front of the patient, in view of other professionals, or in the medical record can be demoralizing. The priority is to communicate effectively with the surgical team responsible for the patient and to encourage that team to make final decisions.

Ambiguity

Another vexation occurs when an urgent request is not connected to a clear rationale (Chapter 398). Diplomacy is needed to establish whether the motivation reflects a medicolegal concern rather than a biologic change in the patient.

Sometimes the stimulus for the consultation can best be addressed by providing reassurance and confirmation. Sometimes the stimulus is an obscure preexisting disorder (e.g., Moyamoya disease), and the surgical team has neither the experience nor the time to investigate how this unrelated medical condition can influence recovery from surgery. Sometimes the stimulus is an unspoken political wish to transfer the care of a burdensome patient from one physician to another. A consultant should develop an understanding of how to interact with other clinicians under such ambiguous circumstances.

SETTING PRIORITIES

Requests for consultation often arrive outside conventional working hours, are usually tinged with a sense of urgency, and sometimes cluster to encompass more than one patient. Developing an effective method for prioritizing patients is a crucial clinical skill. One communication strategy is to provide an objective estimated time of arrival for the initial request from the surgical team. An often-helpful treatment strategy is to make some safe suggestions at the time of the initial request so that clear-cut recommendations can be instituted during the interval before the patient is seen and used later to help evaluate the patient's status and course.

AFTERMATH

In many postoperative cases, the original reason for consultation may resolve and no major issues remain. The situation now provides an opportunity to review the patient, particularly for the appropriate use of unrelated medications. The consultant may often detect excessive medications that were appropriate early in the hospital course but have ceased to be necessary, thereby justifying discontinuation (e.g., diuretics, antibiotics, bronchodilators). Discontinuing medications that have become superfluous requires initiative and wisdom, and the common mistake is to propagate unnecessary medications in stable patients under the rationale of "don't mess with success." The ability to watch the patient for several hours or for a day or two often presents an ideal opportunity for the safe withdrawal of medications. Ironically, discontinuing a treatment sometimes requires more skill, time, and initiative than starting it.

MEDICAL CARE OF PATIENTS WITH PSYCHIATRIC DISEASES

MARSHA N. WITTINK AND S. RYAN GREYSEN

POPULATION HEALTH FOR PERSONS WITH SEVERE MENTAL ILLNESSES

Although patients with severe mental illnesses, such as schizophrenia, bipolar disorder, and debilitating depression and anxiety, constitute 6% of the U.S. population and are among the most complex and costly patients in the health care system. Patients with severe mental illness are nearly twice as likely to be readmitted to the hospital and have longer lengths of stay, thereby generating higher costs of care. These patients also have higher rates of chronic conditions, such as diabetes, lung disease, and cardiovascular disease that lead to declining function and to a premature mortality gap of 15 to 30 years compared with the general population.[1]

In this population, the complex interplay of medical, psychiatric, and psychosocial challenges (e.g., poor housing, transportation, and lack of access to preventive medical care) creates barriers to improving outcomes. Patients with severe mental illness are also affected by cognitive biases of providers, including a therapeutic pessimism that underestimates patients' interest in health care decision-making and assumes that patients will not be able to engage in care or adhere to a treatment. A clinician's pessimism, exacerbated by compassion fatigue and a desire for more collaboration with psychiatric and social services,[2,3] often results in reduced screening and missed opportunities for interventions earlier in the course of disease.[4] Another common bias is diagnostic overshadowing: the tendency to attribute symptoms to psychiatric causes rather than investigating medical causes that could be treated. Since the natural course of many psychiatric conditions tend towards improvement over time, the prevention and acute management of medical conditions present critical opportunities for clinicians to improve the outcomes of patients with severe mental illness.

SPECIFIC HEALTH CHALLENGES FOR PATIENTS WITH SEVERE MENTAL ILLNESS

CARDIOVASCULAR DISEASE

Cardiovascular disease, which is the leading cause of death for people with severe mental illness, is twice as common as compared with the general population. Contributing factors include a higher prevalence of cardiovascular risk factors, such as smoking, sedentary lifestyle, and poor nutrition (Chapter 40); structural disadvantages, including financial, housing, and transportation challenges (Chapter 4); delayed care-seeking; and mistrust of the health care system. Unfortunately, many psychotropic medications, in particular second-generation antipsychotic medications (Table 402-1), are associated with metabolic disorders, diabetes, and cardiovascular disease.

Beyond these patient factors, health care providers contribute to these disparities because patients with severe mental illness are less likely to receive adequate treatment. For example, when patients with severe mental illness suffer an acute myocardial infarction, they are less likely to receive aspirin, beta-blockers, coronary angioplasty, and coronary artery bypass grafting. Similarly, when patients with severe mental illness develop heart failure, they are less likely to have their left ventricular ejection fractions measured. These disparities, which persist even after adjusting for other comorbid illnesses, may be amplified by the use of alcohol (Chapter 364) and drugs of abuse (Chapter 365). Integrating medical and behavioral health in primary care and other settings may be one way to reduce these disparities.[A1]

AGING

The disproportionate burden of morbidity and mortality in the population with severe mental illness is exacerbated by aging, which accelerates the sensory, cognitive, physical, and functional challenges associated with mental illness. These challenges undermine the ability to comprehend and adhere to treatments and to access health information and services. For example, many patients with schizophrenia or major depression have greater cognitive and functional impairment than expected simply by their age or illness, and this

Contributing factors include a higher prevalence of cardiovascular risk factors, such as smoking, sedentary lifestyle, and poor nutrition (Chapter 40); structural disadvantages, including financial, housing, and transportation challenges (Chapter 4); delayed care-seeking; and mistrust of the health care system. Unfortunately, many psychotropic medications, in particular second-generation antipsychotic medications (Table 402-1), are associated with metabolic disorders, diabetes, and cardiovascular disease.

Beyond these patient factors, health care providers contribute to these disparities because patients with severe mental illness are less likely to receive adequate treatment. For example, when patients with severe mental illness suffer an acute myocardial infarction, they are less likely to receive aspirin, beta-blockers, coronary angioplasty, and coronary artery bypass grafting. Similarly, when patients with severe mental illness develop heart failure, they are less likely to have their left ventricular ejection fractions measured. These disparities, which persist even after adjusting for other comorbid illnesses, may be amplified by the use of alcohol (Chapter 364) and drugs of abuse (Chapter 365). Integrating medical and behavioral health in primary care and other settings may be one way to reduce these disparities.[A1]

AGING

The disproportionate burden of morbidity and mortality in the population with severe mental illness is exacerbated by aging, which accelerates the sensory, cognitive, physical, and functional challenges associated with mental illness. These challenges undermine the ability to comprehend and adhere to treatments and to access health information and services. For example, many patients with schizophrenia or major depression have greater cognitive and functional impairment than expected simply by their age or illness, and this

ABSTRACT

Medical conditions are far more prevalent in patients with severe mental illness and are associated with far worse outcomes, including disability and early mortality compared with the general population for several reasons. First, patient factors such as accelerated aging, poverty, social stigma, and unhealthy lifestyle are major contributors to disproportionate medical morbidity. Second, many of the treatment options for managing psychiatric disease (psychotropic medications) have significant side effects that worsen the burden of medical morbidity. Third, provider factors such as cognitive biases can contribute to worse outcomes by delaying the appropriate evaluation and care of medical conditions. This chapter outlines approaches to medical management of patients with severe mental illness in a variety of common settings and suggest strategies to overcome the factors that contribute to poor outcomes. The chapter also reviews common medical complications of psychiatric treatments, including cardiovascular effects (e.g., prolonged QT interval, myocarditis, and myositis), respiratory and swallowing effects (e.g., aspiration and asphyxia), and life-threatening syndromes (e.g., neuroleptic malignant syndrome, serotonin syndrome, and catatonia).

TABLE 402-1 COMMON MEDICAL COMPLICATIONS OF PSYCHOTROPIC MEDICATIONS

MEDICAL COMPLICATIONS		PSYCHOTROPIC MEDICATION CLASS/COMMON MEDICATIONS	PROPOSED MECHANISMS
Cardiovascular	Prolonged QTc/arrhythmia	Antipsychotics SSRIs (citalopram/escitalopram) Tricyclics	Blocking delayed rectifier potassium ion channels
	Cardiotoxicity (myocarditis, cardiomyopathy)	Clozapine	Unknown, possible IgE-mediated hypersensitivity
	Orthostatic hypotension	Trazodone Antipsychotics Tricyclics	Alpha-1 adrenergic receptor antagonism
	Hypertension	Venlafaxine (dose-dependent)	Venlafaxine: norepinephrine reuptake inhibition (dose-dependent)
		MAO-inhibitors	MAO-inhibitors: excess norepinephrine and/or serotonin (mostly with drug-drug or drug-food interactions)
		Antipsychotics	Antipsychotics: unclear
Respiratory	Aspiration	Antipsychotics Tricyclics Benzodiazepines	Antimuscarinic, antihistaminic, anticholinergic: dry mouth, esophageal dilation, and hypomotility Sedation may also play a role.
	Respiratory Depression	Antipsychotics	Suppression of central respiratory drive
Gastrointestinal	Constipation (small bowel obstruction with clozapine)	Antipsychotics: clozapine, olanzapine, mirtazapine Tricyclics	Anticholinergic and possibly antiserotonergic properties
	Dysphagia; sialorrhea	See Table 402-3	See Table 402-3
	Hepatic impairment Hyperammonemia	Anticonvulsant; mood stabilizers: carbamazepine, valproate Antidepressants: mirtazapine Antipsychotics: olanzapine	Idiosyncratic: hypersensitivity reactions and toxin-induced
Renal and urinary tract	Renal insufficiency Urinary retention	Lithium Antipsychotics Tricyclics	Diabetes insipidus with hypernatremia Anticholinergic properties
Endocrine	Hyperprolactinemia	Antipsychotics: risperidone, haloperidol, fluphenazine	Dopamine blockade leads to increased prolactin levels
	Thyroid abnormalities	Lithium	Accumulation in the thyroid gland can alter synthesis and release of thyroid hormone
	Hyponatremia/SIADH	Antipsychotics: carbamazepine, oxcarbazepine	Antipsychotics: D2 receptor blockers
		Antidepressants (most commonly SSRIs/SNRIs)	Antidepressants: sustained release of ADH from the hypothalamus
Hematologic	Neutropenia Agranulocytosis	Clozapine, olanzapine, risperidone, quetiapine	A chemically reactive nitrenium ion, which is a metabolic product, causes direct toxicity or initiates an immune mechanism
	Leukocytosis	Lithium	Unclear cause
	Thrombocytopenia	Valproate, carbamazepine	Drug dependent autoantibodies and direct toxic effect on bone marrow
Skin	Stevens-Johnson syndrome	Lamotrigine Carbamazepine	Cytotoxic T-cell-mediated HLA-dependent drug hypersensitivity
Neurological	Extrapyramidal symptoms	First-generation antipsychotics > second-generation: especially clozapine, bupropion	Antagonism of dopamine D2 receptors
	Seizures	Tricyclics	Lower seizure threshold

ADH = antidiuretic hormone; HLA = human leukocyte antigen; MAO = monoamine oxidase; SIADH = syndrome of inappropriate antidiuretic hormone secretion; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

impairment can progress independently of psychiatric symptoms. Functional and cognitive assessment is imperative for all patients with severe mental illness, regardless of their chief complaint or age. Preventive efforts, such as encouraging engagement in community mental health services, referral for cognitive rehabilitation, and occupational therapy should be considered early. When more severe functional or cognitive impairment is present, planning for long-term support should be considered even while addressing the medical causes prompting acute care.

SUBSTANCE USE DISORDERS

As many as 50% of patients with severe mental illness have substance use disorders (Chapters 364 and 365). Rates of cigarette smoking (Chapter 363) are three-fold higher than in the general population, and patients with severe mental illness smoke more cigarettes for longer periods of time. Unfortunately, systems of care for severe mental illness and substance use disorders are often not integrated, so the likelihood that one of these issues may be undiagnosed or undertreated is higher than for either condition alone.[5] Despite these daunting odds, smoking cessation interventions have been successful when integrated into mental health settings and adapted to meet the needs of patients with severe mental illness.[A2] When caring for patients with a psychiatric diagnosis, it is critical to consider and screen for substance use, which may otherwise represent an added barrier to successful management of psychiatric symptoms. Similarly, when patients with severe mental illness present with agitation or a change in mental status, intoxication and substance abuse should be considered in the medical differential.

PROVIDING CARE IN DIFFERENT SETTINGS

All of the above factors lead to challenges for the physician who cares for patients who have concomitant medical and psychiatric needs. Depending on the psychiatric resources, the medical physician may be tasked with anything from identifying and separating the medical, psychiatric, and cognitive components of an acute change in mental status (Chapter 361) in the emergency department or on a medical service, to comanaging acute respiratory failure (Chapter 90) in a patient with active psychosis (Chapter 362), to providing consultation for chest pain (Chapter 39) to a patient admitted to a psychiatric hospital.

EVALUATION IN THE EMERGENCY DEPARTMENT

Some hospitals have emergency psychiatric resources, including dedicated areas for assessing acute psychiatric emergencies, but many do not. Although a true medical emergency (e.g., stroke [Chapters 376 and 377], coma [Chapter 373], sepsis [Chapter 94], substance overdose [Chapter 96]) must first be excluded in the patient with an altered level of consciousness, patients who have acute symptoms or decompensation of severe mental illness are often managed with the aid of a psychiatric consultation, particularly in hospitals that lack a dedicated psychiatric unit. Even in hospitals that do have psychiatric units, medical stabilization beyond what can be done in the emergency department might require initial admission to a medical unit. In making such determinations, physicians must understand that the criteria for acute admission to a psychiatric unit is often restricted to patients who are at risk for self-harm or harming others and have the potential for improvement on an inpatient psychiatric unit. For example, patients with neuropsychiatric sequelae of dementia may not meet criteria for admission to a psychiatric unit because they are unlikely to benefit from the therapeutic interventions provided there, whereas a bipolar patient with acute mania would potentially benefit. In patients who have relatively stable and chronic psychiatric issues, the key issue often is whether the patient can be safely discharged based on housing stability, social support structure, and transportation needs for follow-up medical care. Social work consultation and other resources can help with safety and the feasibility of outpatient options before a decision is made to discharge a patient.

CONSULTATIONS TO A PSYCHIATRIC UNIT OR HOSPITAL

Physicians who care for patients in psychiatric settings should have a general understanding of the environment and capabilities of the staff before arriving to see a patient. At the systems level, general familiarity with mental health regulatory, organizational, and insurance requirements can be helpful for understanding why patients were admitted, as well as the legal and supportive structures in place to protect the patient's rights. For example, medical and psychiatric beds are separated by regulatory oversight in many states, so transfer from one to the other requires a discharge and new admission. At the environmental level, it is useful to understand policies on locked doors and whether patients may have access to items such as oxygen and intravenous tubing that could pose a risk for self-harm or suicide. At the therapeutic level, it is important to understand how psychiatric units use their milieu to foster interactions among patients in preparation for returning to the community. This notion of using the milieu is often quite different than the environment on medical floors, where patients are rarely encouraged to interact with other patients as part of the care and rehabilitation process. Furthermore the staff and nurses in a psychiatric setting are focused on mental health therapy and are unlikely to be familiar with many medical interventions.

MEDICAL/SURGICAL FLOOR

For patients admitted to a medical unit, several key issues are important for the initial assessment.

Continue Outpatient Psychotropic Medication Regimens

It is very important not to interrupt or delay ongoing psychotropic medication therapy, especially in a patient who has been stable on a specific dose for months or longer. Abrupt discontinuation of some psychotropic medications can lead to withdrawal (also referred to as discontinuation syndrome), relapse of the psychiatric condition, or worsening of ongoing symptoms and behaviors.[6,7] If a reported medication was not taken regularly, however, restarting at the reported dose may lead to unexpected side effects from its rapid initiation. If a strong suspicion suggests that the acute medical problem is related to a known side effect of a psychotropic medication (e.g., see Table 402-1), it is reasonable to hold the medication temporarily while contacting the prescribing or consulting psychiatrist or pharmacist to discuss the relative risks and benefits of the particular medication, the alternative options, and how and when to restart the medication. If the psychotropic medication helps for more than a few days, dose titration may be required.

Obtaining the History of Smoking and Substance Use

Nicotine stimulates dopaminergic activity, which can reduce stress and enhance cognitive ability while stimulating the brain's reward centers. Nicotine withdrawal can exacerbate or lead to agitation. In addition, for patients who are heavy tobacco users, abrupt cessation of nicotine, which induces the CYP1A2 system that metabolizes clozapine and olanzapine, can increase the bioavailability of these drugs and result in over-sedation. For other known or suspected substance use, withdrawal symptoms should be anticipated and appropriate interventions begun (Chapters 364 and 365).

Communication and Building Trust

Somatic delusions and disorganized speech can make communication challenging. Nevertheless, an accurate history and physical examination are possible by observation and communication with others who are caring for the patient. Physicians should engage patients with severe mental illness with an empathetic and unbiased approach, being sure to obtain all relevant information (Chapter 6), but with a degree of flexibility. If patient declines part of the evaluation or treatment, it is important to recall the ethical imperative of do no harm. For example, restraining a patient to obtain a laboratory test or maintain an intravenous line would be warranted only in cases of imminent risk. Taking the time to understand a patient's priorities helps build trust and adherence. For example, a patient with paranoia may have difficulty understanding the importance of monitoring physical symptoms. Consulting with clinicians or other trusted persons who know the patient's preferences and communication style can be very helpful. A team-based care plan can help avoid a situation in which such patients may pit one clinician against another.

Physicians should also anticipate the potential for antagonism between patients and hospital staff owing to stress and unfamiliarity, especially on a medical unit, and proactively address sources of friction to prevent escalation. For example, minimizing nighttime blood drawing and medications can help reduce agitation for patients who are not accustomed to being medically hospitalized. Flexible plans can help build trust and encourage engagement in care. For example, a patient with diabetes may be more willing to engage in treatment if offered more dietary options, even if they are not ideal for glucose control.

Deescalation

The typical pitfall of clinicians is to become defensive when a patient becomes agitated or angry. A critical component of deescalation is recognizing one's own response to a patient. Reacting with fear or anger can lead the patient to become more agitated. An approach that can help deescalate a situation includes first controlling one's own emotional response and then using communication skills to engage the patient. The process is not unlike reacting to an emergency medical situation; in this case the way to control the emergent behavior is by building rapid rapport. A helpful first step is to take the time to show sympathy and ask open-ended questions to understand the patient's frustration. Other techniques include paying attention to body language, avoiding threatening postures, and setting boundaries and limits. Deescalation techniques are invaluable for reducing injuries to other patients or clinical staff and to reducing clinician burnout.

INTEGRATING MEDICINE AND PSYCHIATRY

Models of care that increase coordination between medical and psychiatric services in the outpatient setting, through co-location of primary care and psychiatry services or embedded primary care within specialty mental health settings, can improve outcomes, reduce costs, and improve staff satisfaction, particularly in the outpatient setting.[A3]

An inpatient model is the hybrid medical-psychiatry unit, in which medical and psychiatric physicians manage the treatment of patients admitted for acute medical needs in the context of their psychiatric complexity, or vice-versa.[8] Staff on such units should be skilled in caring for patients with both medical and behavioral health needs, including expertise in deescalation techniques. Medical-psychiatry units that provide comprehensive care and connections to integrated settings may hold the most promise for reducing the risk that patients will fall between the silos of mental and physical health.[9]

MEDICAL COMPLICATIONS OF PSYCHIATRIC TREATMENTS

BRIEF OVERVIEW OF PSYCHIATRIC DRUG CLASSES

Drugs for psychiatric conditions, including antipsychotics, antidepressants, anxiolytics, and mood stabilizers (Chapter 362), are often referred to broadly as psychotropic medications. The mainstay of modern pharmacologic treatment of severe mental illness is a family of drugs commonly known as antipsychotics: first generation (otherwise known as typical or neuroleptic) and second generation (otherwise known as atypical). Other drug classes commonly prescribed to patients with severe mental illness include antidepressants (selective serotonin reuptake inhibitors [SSRIs]; serotonin-norepinephrine reuptake inhibitors [SNRIs]; monoamine oxidase [MAO] inhibitors; and

tricyclic antidepressants), anxiolytics (benzodiazepines), and mood stabilizers (lithium, and anticonvulsant medications such as valproate). Medical consultation in patients with severe mental illness should be informed by knowledge about serious complications of these medications (see Table 402-1).

CARDIOVASCULAR COMPLICATIONS

In addition to the increased risk of atherosclerotic disease and coronary heart disease conferred by lifestyle factors and barriers to access to health care, several classes of psychotropic medications increase the risk for arrhythmias (through prolongation of the QT interval; Table 402-2),[10] cardiomyopathy, and myocarditis. Patients should have a baseline screening electrocardiogram (ECG) and serum electrolyte levels, as well as careful review of any history of syncope, arrhythmias, or early sudden death (before age 40) in first-degree relatives before beginning any antipsychotic medication regimen. If the baseline QTc is greater than 450 msec (men) or greater than 470 msec (women), significant hypokalemia (serum potassium level <3.5 mEq/L) or hypomagnesemia (serum magnesium level <1.5 mg/dL) should be repleted before starting psychotropic therapy. At the same time, a prolonged QTc should prompt reconsideration of risks and benefits before initiating psychotropic medications. After therapy is initiated, 12-lead ECG and electrolytes should be repeated at least annually, after any increase in the antipsychotic drug dosage, or after the addition of other drugs known to prolong the QT interval or cause electrolyte abnormalities, particularly of potassium or magnesium. Semi-annual monitoring may be indicated in older patients and patients with known structural or coronary arterial disease. An ECG also should be obtained immediately in any patient who develops the new onset of palpitations, syncope/near-syncope (Chapter 49), falls, or chest pain (Chapter 39) while taking antipsychotic medications.

QTc intervals less than 500 msec but longer than 450 msec in men and 470 msec in women should prompt reevaluation of the risks and benefits associated with the drugs in question, repletion of the potassium level to above 4.0 mEq/dL and magnesium level to above 2 mg/dL and a repeat ECG within 2 to 4 weeks.[11] A corrected QT (QTc) interval of 500 msec or longer should prompt cardiology consultation and immediate discontinuation of all medications known to prolong the QTc interval.

TABLE 402-2 COMMON PSYCHOTROPIC MEDICATIONS AND RISK OF QTc PROLONGATION

PSYCHOTROPIC MEDICATIONS (GENERIC)	BRAND NAME	AVERAGE AMOUNT OF PROLONGATION OF QTc (MSEC)
ANTIPSYCHOTICS		
Thioridazine	Mellaril	28-37
IV Haloperidol	Haldol	16
Ziprasidone	Geodon	16
Quetiapine	Seroquel	15
Risperidone	Risperdal	10
Clozapine	Clozaril	10
PO Haloperidol	Haldol	4-9
Olanzapine	Zyprexa	6
Lurasidone	Latuda	5
Paliperidone	Invega	4
Aripiprazole	Abilify	Negligible effect
Perphenazine	Trilafon	Negligible effect
ANTIDEPRESSANTS: SSRIS		
Citalopram	Celexa	10-20
Escitalopram	Lexapro	5-11
Fluoxetine	Prozac	Negligible effect
Fluvoxamine	Luvox	Negligible effect
Paroxetine	Paxil	Negligible effect
Sertraline	Zoloft	Negligible effect
ANTIDEPRESSANTS: SNRIS		
Desvenlafaxine	Pristiq	Negligible effect
Duloxetine	Cymbalta	Negligible effect
Venlafaxine	Effexor	Negligible effect
ATYPICAL ANTIDEPRESSANTS		
Trazodone	Desyrel	4-7
Bupropion	Wellbutrin	Negligible effect
Mirtazapine	Remeron	Negligible effect

IV = intravenous; PO = oral; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

Myocarditis and cardiomyopathy (Chapter 47) are also more common in patients who are treated with antipsychotic medications, especially clozapine.[12] The myocarditis often occurs unexpectedly within 3 weeks of starting therapy. Patients require close monitoring, especially after the initiation of therapy, with a low threshold to evaluate any new symptoms consistent with myocarditis, including fever, dyspnea, myalgias, fatigue, or chest pain with cardiac biomarkers (e.g., a troponin level) ECG, and transthoracic echocardiogram (Chapter 47). Symptoms often resolve or improve significantly with removal of the inciting agent, but mortality can be as high as 50%. Clozapine can also lead to dilated cardiomyopathy over longer periods of treatment (typically 6 to 9 months). Although the mortality is lower than for clozapine-induced myocarditis, clinicians should have a low threshold to pursue echocardiography in patients with new-onset symptoms of heart failure after starting antipsychotic therapy.

METABOLIC SYNDROME

Patients with severe mental illnesses have a sedentary lifestyle and are at high risk of developing the metabolic syndrome, which is characterized by insulin resistance, hypertension, dyslipidemia, and obesity and is associated with an increased risk for the development of diabetes and cardiovascular disease.[13] Up to 40% of patients receiving long-term treatment with antipsychotic medications have impaired glucose tolerance, and about 10% have diabetes. All antipsychotic medications are associated with weight gain, but the atypical or second-generation antipsychotic medications (Table 362-12) in particular appear to be a cause. Clozapine and olanzapine have the highest risk for weight gain and the development of metabolic syndrome, whereas quetiapine, risperidone, and paliperidone carry slightly lower risk. The lowest-risk antipsychotics appear to be the first-generation antipsychotics.

Because the glucose intolerance often seen in patients treated with antipsychotic agents is due to insulin resistance (Chapter 210), it is best treated by aggressive weight reduction (Chapter 201), increasing physical activity (Chapter 14), and metformin (Chapter 210) or a combination of these approaches. For example, metformin (850 mg twice daily) can significantly reduce the weight gain and reverse the metabolic abnormalities associated with the initiation of second-generation antipsychotic drugs,[A4] and a daily dose of 750 to 2500 mg for 12 to 16 weeks may prevent weight gain if it is initiated at the onset of olanzapine treatment. The administration of the glucagon-like peptide-1 receptor agonist liraglutide (starting with a dose of 0.6 mg administered subcutaneously daily and uptitrating to 1.2 mg daily after 1 week and to 1.8 mg daily in the third week) to overweight or obese patients treated with olanzapine or clozapine can lead to weight loss, decreased waist circumference and low-density lipoprotein cholesterol levels, and improved glucose tolerance.[A5]

Weight and body mass index should be tracked, particularly in the first 6 months after the initiation of or change in the dose of antipsychotic medications. Blood pressure and blood glucose levels should be monitored every 3 months. Reducing the risk of developing metabolic syndrome is a formidable challenge for physicians caring for patients with severe mental illnesses, but a structured approach can improve cardiovascular risk factors.[A6]

RESPIRATORY COMPLICATIONS: ASPIRATION AND DYSPHAGIA

Asphyxia deaths from choking are about 100 times greater in patients with severe mental illness than in the general population, and many patients who survive a choking incident will have silent aspiration. About 50% of patients with severe mental illness and dysphagia have a fast-eating syndrome with restlessness, poor chewing skills, food pocketing in the cheeks, and an attention deficit. Many medications used in psychiatric treatment also can lead to a range of conditions that affect a patient's ability to swallow and effectively protect their airway (Table 402-3). Furthermore, the anticholinergic properties of first-generation antipsychotics (and less commonly, second-generation antipsychotics) can cause xerostomia, bronchospasm, and even dyskinetic dysphagia,[14] which presents as extreme, often sudden pain and spasm in the anterior cervical region that can be associated with other extrapyramidal symptoms such as torticollis, trismus, or tongue protrusion.[15] Patients with asthma (Chapter 75) or chronic obstructive pulmonary disease (Chapter 76) may be at even higher risk of bronchospasm, pneumonia, and acute respiratory failure. Patients with severe mental illness also are at higher risk of stroke and vascular dementia (Chapter 371), which can predispose them to dysphagia, aspiration, and pneumonia. Interprofessional resources such as speech and language pathology therapists can be very helpful in managing patients who have aspiration or dysphagia.

TABLE 402-3 CAUSES OF ASPIRATION AND ASPHYXIA IN PATIENTS WITH SEVERE MENTAL ILLNESS

CONDITION	SYMPTOMS	ETIOLOGY	TREATMENT
Bradykinetic dysphagia	• Reduced lingual range of motion • Increased oral transit time • Decreased pharyngeal peristalsis • Delayed swallowing reflex	Antidopaminergic and anticholinergic effects of antipsychotic medications, especially haloperidol, lurasidone, and risperidone	Discontinuation or reduced dose of offending medication
Dyskinetic dysphagia	• Involuntary contractions of the tongue and perioral musculature • Clumsiness of voluntary movements of the tongue • Discontinuous propulsion of food bolus in the mouth	Extrapyramidal symptoms Acute dystonia (within 48 hours of starting or a rapid dose increase) or insidious onset of chronic symptoms with long-term use (>1 year) as part of tardive dyskinesia	Vesicular monoamine transporter inhibitors: (deutetrabenazine 6 mg orally twice daily or valbenazine 40 mg orally daily)
Laryngeal dystonia	• Clinical emergency, life-threatening • Laryngeal muscle spasms causing dysphonia, stridor, and respiratory distress	Antiepileptics, dopamine agonists, antipsychotics with anti-dopaminergic effects (first generation much more than second generation)	Prompt administration of intravenous diphenhydramine (25-50 mg intravenously) and discontinuation of offending medication
Sialorrhea	• Drooling and poor oromotor control	Cholinergic effect of phenothiazines, clozapine, olanzapine, and quetiapine	Anticholinergic agents: e.g., oral glycopyrrolate, 1 mg three times daily; oral hyoscyamine, 0.125 mg every 4-8 hours with immediate release or 0.375 mg every 8-12 hours with extended release; ipratropium (1-2 metered sprays of 21 µg per metered dose), or atropine (1-2 drops of 1% solution sublingually, up to twice a day)

CATATONIA, NEUROLEPTIC MALIGNANT SYNDROME, AND SEROTONIN SYNDROME

Catatonia and the related neuroleptic malignant syndrome and serotonin syndrome present with prominent motor and behavioral manifestations. Neuroleptic malignant syndrome and serotonin syndrome often present with features of catatonia and may lie on a spectrum (Table 402-4).

Catatonia

Catatonia is a psychomotor syndrome that can occur in association with primary psychiatric conditions or secondary to medical or neurologic conditions or substances. The incidence of catatonia in the acute inpatient psychiatric setting is 5 to 10%.[16] Although its pathogenesis remains unclear, patients with catatonia have increased cerebral blood flow in the supplementary motor cortex and reduced flow to frontal and insular gray matter. Catatonia can be hyperkinetic and excited (with impulsivity, restlessness and agitation) or hypokinetic and stuporous (with signs such as mutism and psychomotor slowing). Delayed recognition of catatonia can result in serious complications, including rhabdomyolysis, aspiration, thromboembolic disease, and even death. New-onset catatonia, especially when occurring in medical/surgical settings or in older adults, deserves a medical evaluation that prioritizes central nervous system causes such as inflammatory conditions (e.g., paraneoplastic and limbic encephalopathy) and seizures.[17] The diagnosis can be confirmed by improvement after a challenge dose of a benzodiazepine (typically 1 to 2 mg of lorazepam intravenously) under expert supervision. If no change in symptoms is noted within 5 minutes, an additional 1 to 2 mg of lorazepam can be given.

TREATMENT

Once the diagnosis is confirmed or strongly suspected based on initial improvement after the challenge dose, clinical management includes continued treatment with benzodiazepines (typically 2 mg lorazepam orally three to four times daily for 2 to 3 days). Even while managing symptoms, the concurrent identification and treatment of underlying medical or neurologic conditions that could have triggered the catatonia should be undertaken. If no improvement in symptoms is seen in several days, expert psychiatric consultation is required to consider options such as electroconvulsive therapy or amantadine. Frequent assessment of vital signs, pulse oximetry, and monitoring of the osmolar gap are appropriate. Flumazenil (0.2 mg intravenously can be increased to 0.3 mg and then 0.5 mg every minute) should be given when respiratory status is a concern and be continued until respiratory depression resolves. Adding a nonsedating glutamate antagonist agent, either memantine (10 mg daily) or amantadine (100 mg daily), may allow for lower benzodiazepine dosing.

Neuroleptic Malignant Syndrome

Although any dopamine D2 receptor blocking agent, including common antiemetics, can cause neuroleptic malignant syndrome, the risk is lower with second-generation antipsychotics as compared with first-generation antipsychotics. About one-third of cases may present within 48 hours after beginning the offending drug. Most other cases occur within 1 month, but the average time to onset is about 50 days for clozapine. Abrupt discontinuation of a dopaminergic agent may cause parkinsonism-hyperpyrexia syndrome, whose features are indistinguishable from neuroleptic malignant syndrome.

TREATMENT

Neuroleptic malignant syndrome is a serious condition requiring medical attention, often in an intensive care unit, with close monitoring and supportive care.[18] Causative agents should be discontinued, and any associated dehydration or electrolyte imbalances must be addressed. Symptomatic treatment of catatonic symptoms is with benzodiazepines (e.g., lorazepam 1 to 2 mg of IV every 4 to 6 hours). In more severe cases with rhabdomyolysis from muscle rigidity and autonomic instability, alternative medications include bromocriptine (2.5 mg orally or via nasogastric tube every 6 to 8 hours) or amantadine (100 mg orally or via nasogastric tube, daily). In patients with fulminant manifestations with malignant hyperthermia, dantrolene (1 to 2.5 mg/kg IV) may be added with caution given its potential risk of hepatotoxicity. Untreated, neuroleptic malignant syndrome has a reported mortality rate of 10 to 20%, but most deaths are avoidable with prompt diagnosis, early discontinuation of the offending medication, and assertive treatment

Serotonin Syndrome

Serotonin syndrome, which results from excess central and peripheral serotonergic agonism, may be an adverse effect of a single medication (e.g., overdose on a selective serotonin reuptake inhibitor) or due to an interaction among multiple serotonergic agents. The syndrome usually occurs in minutes to hours after starting the offending agent and nearly always occurs within 24 hours.

TREATMENT

Treatment includes immediate withdrawal of offending agents, treatment of catatonia with benzodiazepines, (e.g., lorazepam 1 to 2 mg IV) supportive therapy, and often treatment with the anti-serotonergic agent cyproheptadine (initial dose of 12 mg orally followed by 2 mg every 2 hours until a response is seen). Once the serotonin syndrome resolves, clinical indications for any discontinued medications should be reviewed to prevent relapse.

APPROACH TO COMMON SYMPTOMS AND FINDINGS

Patients with severe mental illness often have somatic complaints (Table 402-5) that frequently generate medical consultation or transfer from a psychiatric unit to a medical unit.

TABLE 402-4 CHARACTERISTICS OF NEUROLEPTIC MALIGNANT SYNDROME AND SEROTONIN SYNDROME

		NEUROLEPTIC MALIGNANT SYNDROME	SEROTONIN SYNDROME	CATATONIA
Precipitated By		Dopamine antagonists, particularly high-potency, first-generation antipsychotics (e.g., haloperidol, fluphenazine) and, to a lesser extent, second-generation agents (e.g., clozapine, risperidone, olanzapine) Metoclopramide, prochlorperazine	Serotonergic agents: consider with two or more serotonergic medications or concomitant substance use (e.g., MDMA) Decreased reuptake of serotonin: SSRIs, SNRIs, TCAs, trazodone, St. John's wort Inhibited serotonin metabolism: MAO inhibitors (including linezolid)	Medical, neurologic and psychiatric conditions
Onset		Variable, 1-3 days	Variable, <12 hours	Variable, days to weeks
Resolution		Days to weeks	<24 hours	Days to weeks
Identical Features	Vital signs	Hypertension, tachycardia, tachypnea, hyperthermia (>40° C)	Hypertension, tachycardia, tachypnea, hyperthermia (>40° C)	Hypertension, tachycardia, tachypnea, hyperthermia (>40° C); autonomic abnormalities may occur ("malignant catatonia")
	Mucosa	Hypersalivation	Hypersalivation	Variable
Overlapping Features	Skin	Diaphoresis, pallor	Diaphoresis	Variable
	Mental Status	Variable: from coma to alert (agitation rare)	Variable: from coma to agitation	Variable: from stupor to agitation
	Muscles	"Lead-pipe" rigidity in all muscle groups	Increased tone, especially in lower extremities	Rigidity, waxy flexibility or paratonic rigidity common
	Laboratory Findings	Elevated CK, WBCs	Elevated CK	Variable (low serum iron catatonia is a risk factor for neuroleptic malignant syndrome)
Distinct Features	Reflexes	Hyporeflexia	Hyperreflexia, clonus (unless masked by increased muscle tone)	Normal
	Pupils	Normal	Dilated	Normal
	Bowel Sounds	Normal or decreased	Hyperactive	Normal
Treatment		Remove offending agent Benzodiazepines (for catatonia) Supportive care Bromocriptine, dantrolene, or amantadine	Remove offending agent(s) Benzodiazepines (for catatonia) Supportive care Cyproheptadine (occasionally)	Benzodiazepines (first line) ECT for malignant or treatment-resistant cases Amantadine or memantine (second line) Treatment of underlying condition

CK = creatine kinase; ECT = electroconvulsive therapy; MAO = monoamine oxidase; MDMA = 3,4-methylenedioxymethamphetamine; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant; WBC = white blood count.

Physicians should be aware that calls from a psychiatric unit about medical concerns may be different than those from other units in the hospital. At times, a nurse or other unit staff member may call for consultation directly, and some consultations may be driven by protocol (e.g., after a fall, altercation, or other trauma). Sometimes, the only observation is that the patient seems less well, without a traditional chief complaint. For example, a unit manager may call to say that a patient is noted to be breathing irregularly but denies dyspnea, cough, or other respiratory symptoms. These concerns, which require a personal visit and examination, should be managed thoughtfully; reassurance to staff and patients is often of high value when an evaluation finds no important underlying medical cause.

DISTINGUISHING AN ACUTE MEDICAL PROBLEM FROM A MEDICATION SIDE EFFECT

Patients with severe mental illnesses, particularly patients who have psychotic disorders, may have unique ways of articulating symptoms. Lower health literacy may result in difficulty communicating physical symptoms, and cognitive impairment and thought disorders can make it difficult for physicians to assess the history and course of illness. Associated lack of motivation can provide further obstacles for understanding a patient's needs. Patients may be vague or silent about physical suffering, or they may describe symptoms in ways that are unusual. The problem of overlapping symptoms (e.g., somatic manifestations of anxiety or anxiety due to physical disease) add to the complexity. Taking a systematic approach to the evaluation and using a structured method for considering the differential diagnosis is paramount. Collateral information from family members and others who know the patient becomes key in such situations. Close collaboration with the patient's mental health or social service providers is additionally helpful in ascertaining what is considered baseline behavior.

Physicians who provide medical care to patients who are taking psychotropic medications also must be aware of the extensive side effect profiles for these medications. Accordingly, the initial evaluation of an acute medical problem should always include the usual comprehensive history, physical examination, and laboratory testing, but also a higher index of suspicion for side effects of psychotropic medications[19] compared with other common classes of medications (e.g., statins, antihypertensive agents, antibiotics, etc.).

When careful evaluation results in a reasonable likelihood that a side effect of a psychotropic medication may be causing or contributing to an acute medical problem, the preferred strategy is usually to continue effective medications but to adjust their dosing or frequency if possible. An alternative strategy is to consider symptomatic management with pharmacologic or behavioral interventions. If these interventions are not successful, the psychotropic agent may need to be discontinued and replaced with an alternative under expert supervision.

GIVING RECOMMENDATIONS

Providing clear and actionable recommendations for the evaluation and management of medical conditions in patients with severe mental illness can improve the care of these patients. Consulting physicians should strive to follow common sense or "golden rules" of consultation; a non-exhaustive list of domains and examples are provided in Table 402-6.

The specific words used to document recommendations can have lasting impact on how patients are treated by current and subsequent clinicians. Medical physicians should strive to use patient-centered words that do not stigmatize: "declined" instead of "refused;" "substance use disorder" instead of "addiction;" "alcohol use disorder" instead of "alcoholic." Finally, consulting physicians should cultivate a sense of self-awareness and practice of examining their reactions and responses to encounters with patients with severe mental illness. Patients who have severe mental illness often have had prior traumatic experiences and interactions with providers and can, at times, be confrontational or otherwise uncomfortable. These interactions may evoke unhelpful emotional responses from providers and adversely influence their

TABLE 402-5 COMMON SYMPTOMS AND FINDINGS IN PATIENTS WITH SEVERE MENTAL ILLNESS

SYMPTOM	UNIQUE FACTORS TO CONSIDER IN PATIENTS WITH SEVERE MENTAL ILLNESS
Chest pain	• Increased risk of CVD in patients on psychotropic medications • Myocarditis and arrhythmias more prevalent
Pain	• Often have a higher pain threshold, so acute illness (e.g., appendicitis) may take longer to recognize • Reported pain may be incongruent with findings, physical examination, or laboratory data
Altered mental status	• Substance use disorders more prevalent • Psychotropic medications recently increased, added or restarted (when previously not adherent) or stopped in the hospital • More prone to cognitive decline, which can precipitate delirium in the hospital
Constipation/urinary retention	• Psychotropic medications can cause severe constipation, lower threshold for considering obstruction • Anticholinergic medications increase risk for constipation and urinary retention, leading to delirium
Hyperammonemia	• Valproic acid
Azotemia	• Psychotropic medications (e.g., quetiapine, risperidone, and olanzapine)
Anemia	• Lithium (microcytic) • Nutritional deficiencies common (iron and vitamin B_{12})
Fever	• Drug overdose (psychostimulants, antidepressants, lithium, anticholinergics) • Bacteremia in setting of intravenous drug use • Alcohol or drug withdrawal (benzothiazines, barbiturates, antiparkinsonian agents) • MAO inhibitors • Serotonin syndrome, neuroleptic malignant syndrome
Hyponatremia	• Polydipsia/water toxicity, SIADH (SSRIs, SNRIs, atypical antipsychotics, mood stabilizers)
Hypernatremia Diabetes insipidus	• Lithium
Trauma	• Higher incidence of trauma (falls, assault, abuse), which patient may minimize or not recall • Low threshold for plain films to assess for fractures, particularly of hands, arms (distal radius), face, spine
Seizure	• Bupropion, MAO inhibitors, tricyclic antidepressants, phenothiazines, clozapine
Hypoxemia	• Aspiration is common; consider aspiration pneumonia if acute or aspiration pneumonitis if chronic
Metabolic syndrome	• Atypical/second-generation antipsychotics • Sedentary lifestyle

CVD = cardiovascular disease; MAO = monoamine oxidase, SIADH = syndrome of inappropriate antidiuretic hormone secretion, SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

TABLE 402-6 BEST-PRACTICE CONSIDERATIONS FOR MAKING RECOMMENDATIONS

DOMAIN	DO	DO NOT	EXAMPLE
Evaluation	Prioritize tests to exclude serious medical conditions, especially if acute signs or symptoms that may have an impact on inpatient care.	Recommend extensive evaluation to exclude less likely causes in the differential, especially in agitated patient.	Prioritize ECG for cardiac condition; avoid serial troponin levels or telemetry unless active myocardial infarction suspected.
Ongoing psychiatric treatment	Consider psychotropic medications as the potential cause or amplifier for new complaints.	Recommend significant modification of antipsychotic medications without consulting the psychiatry team.	Avoid pithy recommendations such as "Switch clozapine to aripiprazole."
Care setting	Align primary treatment goal (medical vs. psychiatric) with patient care setting; stabilize medical conditions to focus on psychiatric care.	Transfer the patient to another inpatient unit unless the primary goal has changed or the required evaluation or treatment cannot be delivered in the current setting.	Acute medical decompensation (e.g., myocardial infarction or acute respiratory failure) requires transfer to a medical unit, but stable angina or mild aspiration may be managed in a psychiatric unit.
Patient-centered documentation	Describe structural determinants of health, such as housing insecurity, transportation challenges, and mental distress.	Portray patient with severe mental illness as uncooperative, unreliable or difficult.	Instead of "poor historian," consider mentioning challenges the patient is having with communication or noting that the history is incomplete until further information can be gathered.
Follow-up care	Include anticipatory guidance, appropriate follow up with suggested time frame, and education for primary team.	Provide excessive details on mechanisms or pedantic statements that do not provide concrete guidance.	Provide specific guidance on what to do if symptoms reoccur or persist and/or when to repeat tests or consider new tests.

ECG = electrocardiogram.

recommendations. The goal is not to prevent or avoid emotional responses; rather the goal is to recognize and process these responses in the most nonjudgmental way.

ONGOING AMBULATORY MEDICAL CARE OF THE PSYCHIATRIC PATIENT

The ongoing medical care of patients who have severe mental illnesses typically is best achieved in community mental health settings that can provide tailored approaches to chronic medical conditions.[20] However, regardless of where patients with severe mental illnesses receive their medical care, close collaboration among all the patient's health care providers is critical.

Illness anxiety disorder (formerly known as hypochondriasis), is the persistent fear of a having a disorder despite normal medical workup and reassurance. For such patients, frequent preemptive office visits with a consistent and supportive medical team as well as engagement in mental health treatment are most effective in reducing the ineffective use of health care resources.[A7]

403 APPROACH TO SKIN DISEASES

CHRISTINE J. KO

A thorough skin examination is about *sape vedere*, "knowing how to see" the skin. Although many nondermatologists often may feel limited to distinguishing a rash from a neoplastic process, it is important for all clinicians to recognize common as well as morbid and life-threatening skin diseases and to refer lesions suggestive of serious disease to a dermatologist.[1] Even as remote "tele-dermatology" has become increasingly available and useful, especially in rural settings,[2,3] data suggest that an in-person examination is still preferable, at least for potentially important diagnoses.[4]

The American Cancer Society and the American Academy of Dermatology advocate routine skin cancer screening for adults on an annual basis, but the U.S. Preventive Services Task Force does not, even for high-risk individuals. Lesion-directed examination of patient-identified abnormalities and screening of people with atypical moles or more than 50 moles may be a reasonable middle ground.[5] Regardless of the frequency of routine total body skin examination, all clinicians should recognize concerning skin lesions, including brown/black/blue/red lesions that are asymmetric and irregular, lesions that look different than others on a given patient, and new lesions that are not healing over 3 to 4 weeks of time (Chapter 188).

STRUCTURE AND FUNCTION OF THE SKIN

A basic understanding of the structure and function of the skin provides a framework for organizing skin diseases. The functions of the skin include physical and mechanical protection, thermoregulation, immunologic surveillance, and sensation. To achieve these goals, the skin is composed of the epidermis, dermis, and subcutaneous tissue. The epidermis is complex, primarily composed of keratinocytes in differentiated layers (E-Fig. 403-1). In addition to the epidermis, epithelial cells form important structures, including hair follicles, eccrine glands, apocrine glands, nails, and hair. Other cell types resident within the skin include melanocytes, Merkel cells, and immune cells. Melanocytes are critical for protecting against damage from ultraviolet light. Langerhans cells are resident immune cells that present antigens to circulating immune cells, which come in and out of the skin more transiently. Within the dermis, the fibroblast is a major cell responsible for forming collagen, which is the key structural protein. Vessels and nerves within the dermis are important for appropriate blood flow and sensation.

APPROACH TO A SKIN PROBLEM

Any new skin problem should be categorized as a tumor or a non-neoplastic process (rash). Although this distinction is often simple, with tumors being solitary and rashes being more diffuse with multiple lesions, there are many exceptions. For example, tinea corporis can present as a solitary, scaling, pink plaque, as can superficial basal cell carcinoma or squamous cell carcinoma in situ (E-Fig. 403-2). Cutaneous T-cell lymphoma can present as multiple, asymptomatic pink patches and plaques, and it can easily be mistaken for a benign rash (E-Fig. 403-3). Knowledge of these pitfalls can help avoid them, with a low threshold for biopsy as clinically indicated.

APPROACH TO DIAGNOSIS

THE SKIN EXAMINATION

Dermatology is an inherently visual specialty, in which subjective perceptions can lead to diagnostic errors,[6,7] which can be reduced by a systematic, orderly approach.[8,9] An observational checklist (Table 403-1) can help guide the skin examination, which is aided by optimal lighting, including side lighting. Magnification can be helpful, and a simple hand lens can be used. Polarized magnifiers (dermatoscopes) can sometimes be helpful for physicians with sufficient training and experience, especially for the diagnosis of possible melanoma.[10]

THE PATIENT

General and more specific characteristics of the patient should be observed. Age, gender, and skin type can all help direct the differential diagnosis. Skin type can be categorized (E-Table 403-1), and hair and eye color should also be noted. Red hair is associated with melanocortin-1 receptor mutations and an increased risk (about two-fold) of melanoma (Chapter 188). Occupational marks (e.g., linear burns on the arms of a baker) can sometimes be clues to job- or hobby-related diseases.

DISTRIBUTION

The bodily distribution (see Fig. 408-13 and Table 408-5) of lesions and the layers of skin (epidermis, dermis, subcutaneous) they involve can be helpful in creating a differential diagnosis (E-Fig. 403-4; Table 403-2). For example, involvement of much of the face, arms, and upper chest in a photodistribution (sparing the skin under the nose, mid-chin, body folds, clothed areas) can point to sun-exacerbated diseases such as lupus erythematosus

TABLE 403-2 LOCATION OF SKIN LESIONS AS A DIAGNOSTIC CLUE

LOCATION	POSSIBLE DIAGNOSES	
Unilateral	Herpes zoster Herpes simplex Deep vein thrombosis	Contact dermatitis where exposed Cellulitis Necrotizing fasciitis Solitary skin malignancies
Bilateral, widespread	Hematogenously spread process Severe drug eruption Disseminated viral, bacterial, or fungal infection Vasculitis Autoimmune disease	Psoriasis Cutaneous T-cell lymphoma Scabies Urticaria Atopic dermatitis (eczema) Other drug eruptions
Bilateral, limited sites	Stasis dermatitis Irritant contact dermatitis	Vasculitis Erythema multiforme Lipodermatosclerosis

TABLE 403-1 OBSERVATIONAL CHECKLIST

WHO?	WHERE?	WHAT?	WHEN?
The patient • General appearance • Age, degree of sun damage • Gender • Skin type, hair/eye color • Occupational marks	**Overall and local distribution** **Depth affected** (can use palpation) • Epidermal • Dermal • Subcutaneous	**Morphology of primary lesion** • Macule (Flat, <1 cm) • Patch (Flat, >1 cm) • Papule (Raised, <1 cm) • Plaque (Raised, >1 cm) • Nodule (Deeper than papule, <1 cm) • Tumor (Deeper than papule, >1 cm) • Vesicle (Fluid-filled, <1 cm) • Bulla (Fluid-filled, >1 cm) • Pustule (Pus-filled, <1 cm) **Configuration/pattern** **Color** **Secondary changes**	**Duration** • Acute • Chronic • Fixed vs. transient

An observational checklist can help guide the general skin examination (see text).

ABSTRACT

A thorough skin examination is about "knowing how to see" the skin. Although many nondermatologists focus on distinguishing a rash from a neoplastic process, it is important for all clinicians to recognize morbid or life-threatening skin diseases. To make the correct diagnosis, the clinician must consider the patient's general appearance; the distribution of skin findings; the morphology, configuration, and color of the skin changes themselves; and nonskin issues. Skin signs with a potential for high morbidity or mortality include generalized sloughing of the skin with red eyes and crusted lips, retiform purpura (concave, netlike, scalloped borders), and pigmented melanocytic lesions that are irregular in color and shape.

KEYWORDS

skin examination
toxic epidermal necrolysis
pruritus
retiform purpura
skin tumor
rash

J

E-FIGURE 403-4, cont'd. I, Dermatomal pattern. J, Blaschko lines. Areas *shaded in red* are classically involved. *Light pink areas* may also be involved. (A to E, From Ko CJ. *Dermatology: Visual Recognition*. Elsevier; 2017. I and J, From Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology*, 3rd ed. London: Saunders; 2012.)

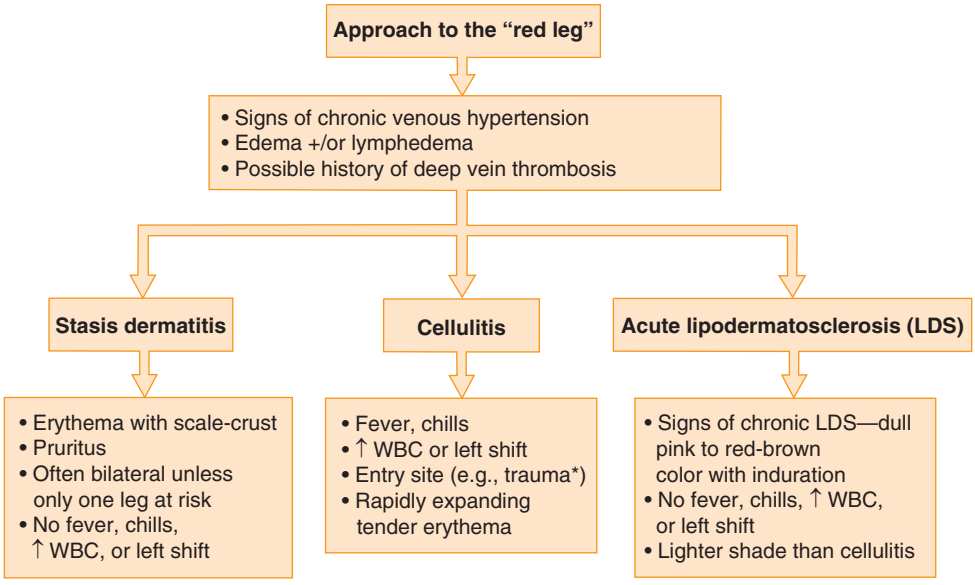

FIGURE 403-1. Approach to the "red leg." *May not have leg at risk. WBC = white blood cells. (From Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology*, 3rd ed. Philadelphia: Saunders; 2012.)

(Chapter 245) or a photo-induced drug reaction (Chapter 25). A unilateral, linear dermatomal distribution of vesicles is highly suggestive of herpes zoster (Chapter 346). Bilateral redness and swelling of the lower legs are highly unlikely to be cellulitis (Chapter 408), which is generally a unilateral disease (Fig. 403-1).

PALPATION

Palpation of lesions can discern the depth of involvement, whether something is more superficial (epidermal), deeper (dermal), or even deeper (subcutaneous) (Table 403-3). Fibrosis, heat, roughness, dimpling, and firmness can also be palpated. Epidermal processes may have associated scale. Dermal disorders can have a normal-appearing surface (a clue that the process is not epidermal) or have overlying epidermal changes as well. Similarly, subcutaneous disorders may affect only the subcutaneous tissue (e.g., erythema nodosum [Chapter 407], which is the most common panniculitis, generally affecting only the adipose tissue) or may affect the epidermis and/or dermis as well (e.g., lupus profundus, in which epidermal and dermal changes are similar to discoid lupus erythematosus [Chapter 245], with necrosis and lymphocytic inflammation within the fat).

MORPHOLOGY

Dermatology has its own vocabulary, and the most basic terms include those for morphology (Table 403-4; and see Table 403-1). The most important descriptions include macule, patch, papule, plaque, nodule, tumor, vesicle, bulla, and pustule. If the clinician is uncertain, descriptive language (e.g., "firm, raised bump about 0.4 cm in diameter" in place of "firm papule") is also effective for communicating among specialists.

Purpura (Fig. 403-2), which is caused by extravasation of red blood cells into the skin, results in a reddish to dark purple to black color. Small, pinpoint purpuric lesions are termed petechiae. Larger areas of purpura are termed ecchymoses. When purpura is palpable, it suggests small vessel leukocytoclastic vasculitis (Chapter 406). Larger vessel systemic vasculitis (Chapter 249) as well as occlusion of smaller vessels can produce retiform purpura, which can be a sign of a life-threatening disorder. The borders of retiform purpura form incomplete rings or nets in a concave outline rather than the smoother, convex, scalloped, and rounded outline of palpable purpura.

CONFIGURATION

The arrangement, or configuration—linear, target, annular/serpiginous, exogenous, small net, or large net—of primary lesions is a principal diagnostic feature, as is its topography—flat-topped, smooth dome-shaped, filiform, pedunculated, verrucous, or umbilicated (Table 403-5). Each of these patterns provides clues to the diagnosis.

COLOR

Color can be an important guide for the differential diagnosis and sometimes is diagnostic (Table 403-6). Importantly, the background skin color can substantially influence the appearance of color within a lesion. For example, inflammation, which usually imparts a pink to red color to the skin, can be masked in darker compared with lighter skin types (E-Fig. 403-5). Lighter skin is at higher risk for skin cancer.

SECONDARY CHANGES

Normal skin does not produce visible scale. The presence of scale indicates that the stratum corneum is abnormal, and different types of scale are clues to the correct diagnosis (E-Table 403-2). Scale is an important component of conditions such as psoriasis, tinea, and pityriasis rosea (Chapter 405). Other secondary characteristics include crusting, fissures, erosion, ulceration, excoriation, atrophy, and lichenification (E-Table 403-3). Certain secondary findings are expected for a given disease—for example, lichenification in atopic dermatitis (Chapter 405) and atrophy in lichen sclerosus (Chapter 407).

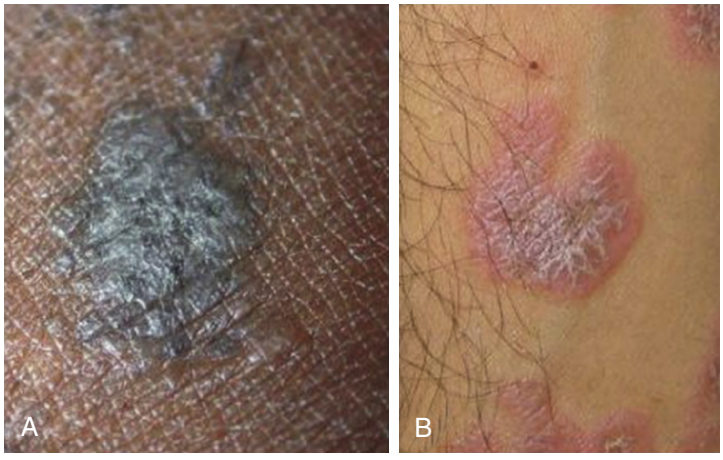
HISTORY

Because dermatologic diagnosis is, for the most part, visually based, the skin examination often precedes taking a history—or the two may be conducted simultaneously. Important factors (Table 403-7) to consider include onset/duration of the problem, systemic symptoms, and lesional symptoms including pruritus and/or pain. The past medical history, list of medications, and contactants, especially if recent or new, are important, as is a review of systems (Chapter 6).

The confidence in a diagnosis increases when the history and the skin findings point coherently to a single diagnostic entity. For example, allergic contact dermatitis (Chapter 405) seems highly likely for a new eczematous, excoriated rash that is seen on the margins of the scalp and extends slightly onto the forehead, especially if it is associated with pruritus and a recent switch to a new hairdresser and use of new hair dye. The differential diagnosis includes seborrheic dermatitis (Chapter 405), which commonly affects the scalp, though less often the forehead, and is often pruritic as well. In this specific example, patch testing (in which patches with specific allergens are placed on the patient's back for 24 to 48 hours before removal) and response to avoidance of hair dye can aid in differentiating the two disorders.

LIFE-THREATENING EMERGENCIES

The presence of an acute fever and rash should prompt exclusion of life-threatening diseases (Table 403-8; Figs. 403-3 to 403-8). Necrotizing fasciitis (Chapter 271) can also be a life-threatening emergency that may be deceptively limited to one extremity. Widespread retiform purpura, including on sites above the waist, in an ill-appearing patient should prompt consideration of



E-FIGURE 403-5. Background skin color. The same disorder, lichen planus, has a completely different color depending on the background darker (**A**) versus lighter (**B**) skin. The purplish tinge seen in **B** is more muted in **A**, which appears gray-purple. Wickham striae (lacy white surface scaling) are more easily seen in **B**. (From Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology,* 3rd ed. Philadelphia: Saunders; 2012:8.)

E-TABLE 403-2 TYPES OF SCALE

UNDERLYING ERYTHEMA

On advancing rim of a ring—e.g., Tinea corporis

Powdery (especially when lightly scraped)—e.g., Tinea versicolor

Greasy—e.g., Seborrheic dermatitis

Silvery to white-yellow—e.g., Psoriasis

Cornflake-like—e.g., Pemphigus foliaceus

Collarette ± central fine scale—e.g., Pityriasis rosea

Wickham striae (fine, net-like)—e.g., Lichen planus

Weeping—e.g., Nummular dermatitis

Lichenified—e.g., Lichen simplex chronicus

E-TABLE 403-2 TYPES OF SCALE—cont'd

WITHOUT UNDERLYING ERYTHEMA

Dry, small polygonal—e.g., Ichthyosis vulgaris

Corrugated, linear—e.g., Epidermolytic ichthyosis

Large, polygonal with lifting of edges—e.g., Lamellar ichthyosis (autosomal recessive congenital ichthyosis)

Scale that is often darker compared with surrounding skin—e.g., X-linked ichthyosis

Photographs from Ko CJ. Dermatology: *Visual Recognition*. Elsevier; 2017; Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology*, 3rd ed. London: Saunders; 2012, and the Yale Dermatology Residents' Collection.

E-TABLE 403-3 MORPHOLOGIC TERMS FOR SECONDARY FEATURES

Crust: Dried serum, yellow to hemorrhagic depending on number of cells in exudate

Impetigo

Fissure: Small linear splits in skin, usually superficial

Hailey-Hailey disease

Erosion: Loss of part of the epidermis

Staphylococcal bullous impetigo

Ulceration: Loss of epidermis into deep dermis or fat

Chronic ulcerated herpes simplex

E-TABLE 403-3 MORPHOLOGIC TERMS FOR SECONDARY FEATURES—cont'd

Excoriation: Self-inflicted erosion or ulcer

Factitial dermatitis (dermatitis artefacta)

Neurodermatitis; note inferior cutoff where patient cannot reach

Atrophy: Thinning or loss of dermal structures or fat usually; may apply to any tissue

Fat atrophy: lupus panniculitis

E-TABLE 403-3 MORPHOLOGIC TERMS FOR SECONDARY FEATURES—cont'd

Lichenification: Thickened skin from chronic rubbing. Poorly demarcated, skin lines accentuated

Lichen simplex chronicus

TABLE 403-4 MORPHOLOGIC TERMS FOR PRIMARY LESIONS

Macule: Flat, nonpalpable, <1 cm diameter

Lentigines. Brown to tan macules.

Papule: Superficial, raised, palpable, <1 cm diameter

Seborrheic keratosis. Gray-black stuck-on papule.

Patch: Large macules >1 cm diameter

Melasma. Light tan patch on the cheek.

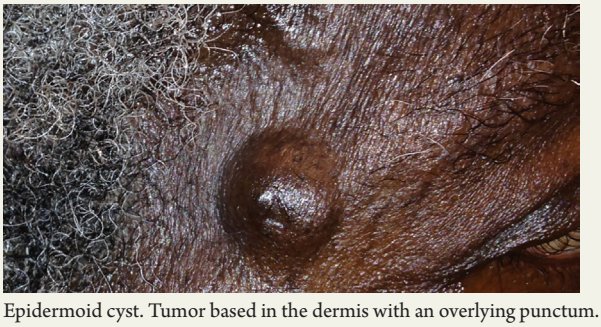
Plaque: Raised, palpable, >1 cm diameter

Psoriasis. Pink-red well-demarcated plaques with adherent scale.

Nodule: Deeper than a papule, usually <1 cm diameter

Gout. Yellow-pink nodules over and near joints.

Tumor: Large mass, >1 cm diameter



Epidermoid cyst. Tumor based in the dermis with an overlying punctum.

Vesicle: <1 cm fluid-filled, may be umbilicated or contain pus or blood

Herpes zoster. Small vesicles, some becoming confluent, with background erythema. The vesicles and erythema are unilateral in a dermatomal distribution.

Bulla: >1 cm, filled with clear fluid, pus, or blood

Bullous pemphigoid. Tense bullae (and some vesicles) on a pink background.

Pustule: White, pus-filled, small, raised, <1 cm diameter

Acute generalized exanthematous pustulosis (a type of drug reaction). Small pustules over confluent erythema.

Photographs courtesy Mary Tomayko, MD, PhD, and from Ko CJ. *Dermatology: Visual Recognition*. Elsevier; 2017; Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology,* 3rd ed. London: Saunders; 2012; Yale Dermatology Residents' Collection; and NYU Slide Collection.

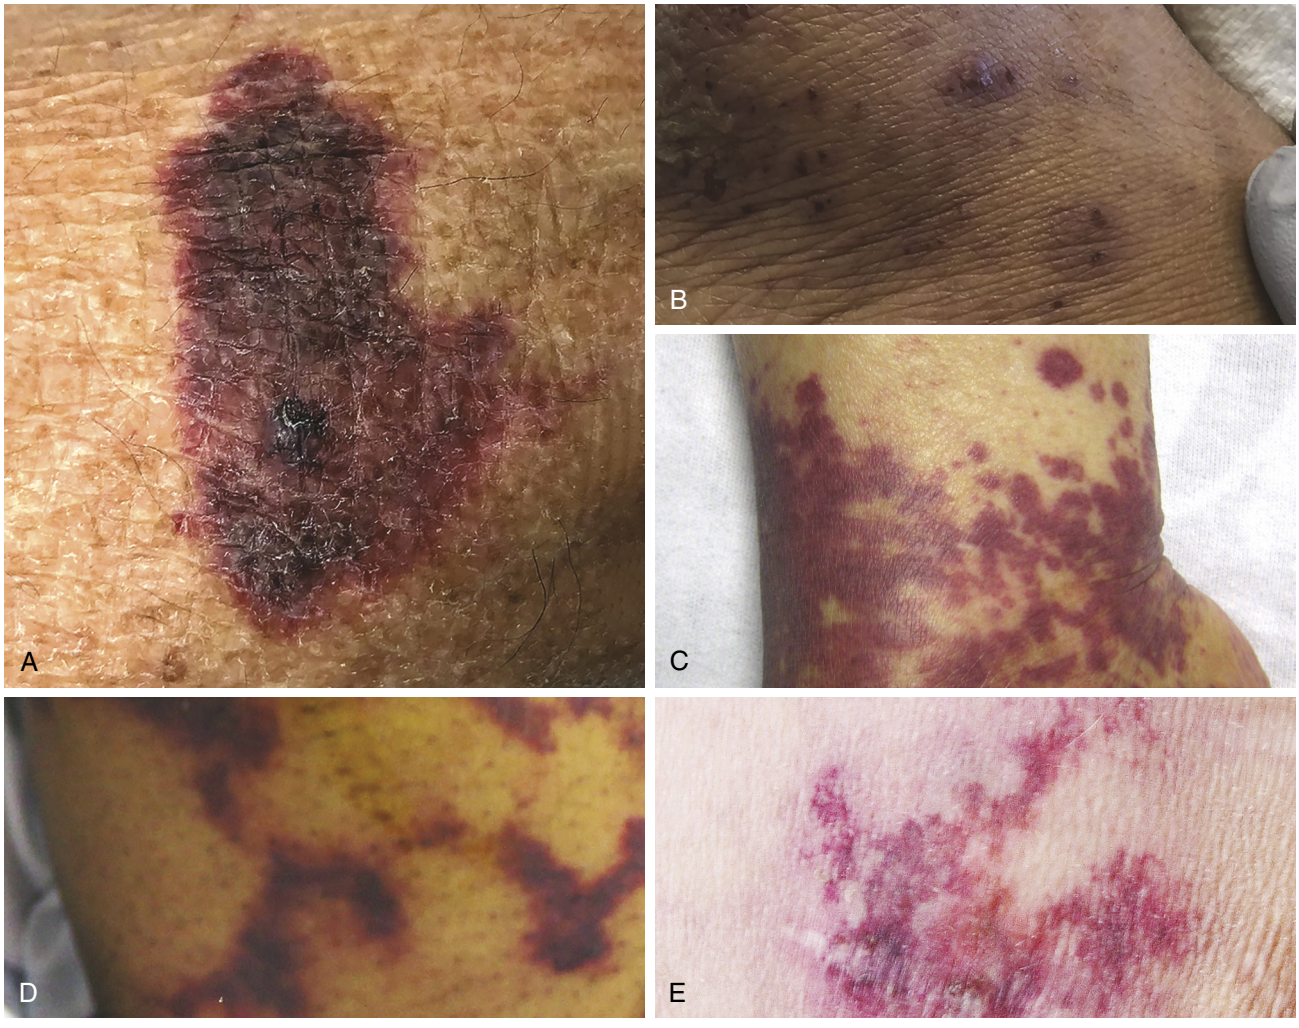


FIGURE 403-2. Purpura represents extravasated erythrocytes in the skin. A, Solar purpura. Bruises on the sun-exposed skin of older individuals are very common. **B, C**, Palpable purpura, which generally corresponds to leukocytoclastic vasculitis on biopsy. In darker skin (**B**), redness can be less obvious and appear more purple-gray in color. **D, E**, Retiform purpura. Note the jagged, netlike outlines. Purpura can vary in color depending on the background skin color. Retiform, or branching, purpura is often associated with larger vessel systemic vasculitis or coagulopathy. (B, Courtesy Yale Dermatology Residents' Slide Collection. C, From Ko CJ. *Dermatology: Visual Recognition*. Elsevier; 2017.)

disseminated intravascular coagulation (Fig. 403-9; Chapter 161), which is seen in severe systemic infections, such as meningococcemia (Chapter 274). The widespread distribution in a sick patient is in sharp contrast to localized purpura, which is less concerning and points to coagulation disorders, including reactions to warfarin or heparin, or the palpable purpura of small vessel leukocytoclastic vasculitis (see Fig. 403-2). Persistent skin mottling, principally in the fingers and toes, is a sign of poor circulation in a critically ill patient and is associated with increased mortality. Intense pruritus accompanying an acute blistering eruption points toward bullous pemphigoid or allergic contact dermatitis (Figs. 403-10 and 403-11; Chapter 405) rather than toxic epidermal necrolysis (Chapter 407).

DIAGNOSTIC TESTS

Pressing on the skin with something transparent (termed diascopy), such as a glass slide or tube, can help confirm the status of vessels, which normally blanch and then refill. Diascopy of red-pink erythema can confirm that the color is inflammatory—the red-pink color should fade completely with pressure. This finding is in contrast to purpura (blood within the skin), which has a deep red to purple to black color that does not fade with pressure.

Scale can always be gently scraped off onto a glass slide with a scalpel blade or even with another microscopic slide. A 10% solution of potassium hydroxide (KOH) can be applied onto the scale, then a cover slip can be placed over the scale and solution, with the bottom of the slide placed briefly over a flame (from a lighter or even a match). KOH dissolves keratin, with the heat accelerating the reaction, thereby allowing nonkeratinized structures such as fungal hyphae to be prominent on microscopic examination (E-Fig. 403-6). If scabies (Fig. 98-2) is suspected, skin lesions can be gently scraped, with scale and crust placed onto a slide covered with a small amount of mineral oil (E-Fig. 403-7).

Rapid diagnosis of herpes virus infection (without speciation) is possible with the Tzanck smear, by which vesicles are unroofed, with gentle scraping of the base of the lesion. Collected material is smeared onto a microscopic slide and briefly heated, with subsequent application of any nuclear stain (e.g., methylene blue, alanine, hematoxylin). After the slide is rinsed and blotted, microscopic examination can identify the pathognomonic multinucleated keratinocytes (E-Fig. 403-8). Other tests include direct fluorescent antibody staining, polymerase chain reaction testing, electron microscopy, and viral culture; local practice patterns often dictate which test is preferred. A Gram stain to look for bacteria is similar: pustular material is smeared and briefly heated on a slide, then four different stains are applied and rinsed (crystal violet, iodine, alcohol, safranin) in order. The slide is blotted, mounted under immersion or mineral oil, and examined under high magnification. Dermoscopy can magnify and/or polarize skin lesions, thereby aiding in visual diagnosis.

A skin biopsy entails taking a small piece of skin for fixation and microscopic examination. In general, the center of lesional tissue should be biopsied; the periphery should be biopsied only for ulcers, bullae, and normal skin for direct immunofluorescence studies.

PRURITUS

Pruritus is the medical term for itch. Pruritus, especially chronic pruritus, can be likened to pain (Chapter 26), as it can be extremely disruptive and life-changing.[11] Both pruritus and pain are mediated by the same nerve fibers, unmyelinated C fibers. Pruritus may originate in the skin (e.g., inflammatory skin diseases such as atopic dermatitis and psoriasis are the most common causes of chronic itching), afferent nerves (e.g., brachioradial pruritus), or the central nervous system (e.g., renal or liver failure, lymphoproliferative disorders, malignancy, delusions of parasitosis). When approaching a patient with

TABLE 403-7 IMPORTANT CLUES FROM THE HISTORY AND GENERAL HEALTH STATUS

CLUES	POSSIBLE DIAGNOSES	
Pruritus (itch)	Atopic dermatitis (eczema) Allergic contact dermatitis Urticaria Scabies	Bullous pemphigoid Lichen planus Dermatitis herpetiformis Inflammatory tinea pedis
Absence of pruritus	Acne vulgaris Rosacea Syphilis	Skin malignancies Lupus erythematosus Pemphigus vulgaris Erythema multiforme
Pain	Herpes zoster Ischemic necrosis from all causes Cellulitis Furunculosis	Carbuncles Pyoderma gangrenosum Severe systemic illnesses
Medications (especially new)	Severe drug eruptions Fixed drug eruptions Morbilliform drug eruptions Immunosuppression	Subacute cutaneous lupus Psoriasis exacerbation Urticaria Drug-induced hair loss
Cachexia/malnutrition	Paraneoplastic dermatoses Skin malignancy Alcohol exacerbated psoriasis	Nutritional deficiencies Metastatic disease Eating disorders leading to nutritional deficiencies
Obesity or weight gain	Dermatoses of diabetes Thyroid disease Cushing disease Polycystic ovarian syndrome Acne	Hirsutism Striae Acanthosis nigricans Eruptive xanthomas
Poor hygiene	Bacterial skin infections Infestations	Substance abuse
Psychiatric illness	Self-inflicted skin disease	Drug-induced dermatoses

TABLE 403-8 APPROACH TO THE ADULT WITH AN ACUTE FEVER AND RASH*

CATEGORY	DISEASES	CLUES ON SKIN EXAMINATION
Infectious	Potentially life-threatening systemic infection (viral, bacterial, fungal†, protozoal†) • Disseminated herpes zoster or herpes simplex† (see Fig. 403-3) • Meningococcemia (see Fig. 403-4) • Toxic shock syndrome (see Fig. 403-5) Disseminated fungal diseases (see Fig. 403-6)† Candidiasis Histoplasmosis Cryptococcosis • Protozoal† Strongyloidiasis Usually not immediately life-threatening • Viral exanthems due to enteroviruses, HHV-6, adenovirus; HIV, varicella; Kaposi varicelliform eruption • Bacterial: staphylococcal scalded skin syndrome, secondary syphilis, disseminated erythema migrans (Lyme disease)	Multiple (>2-3 to 100s), discrete lesions, scattered over body, suggesting hematogenous spread **Herpes viruses:** primary lesion is the vesicle **Meningococcemia:** retiform purpura affecting multiple different body sites, including above the waist **Toxic shock syndrome:** acute erythema of palms/soles **Strongyloidiasis:** periumbilical purpura
Inflammatory	Potentially life-threatening • Toxic epidermal necrolysis (see Fig. 403-7) Usually not immediately life-threatening • Drug reactions (severe drug reactions): morbilliform, serum sickness-like reaction, DRESS, AGEP, erythroderma • Erythema multiforme • Primary cutaneous disorders (e.g., pustular psoriasis) • Rheumatologic disorders (e.g., SLE, vasculitis, Still disease) • Graft-versus-host disease	Confluent erythema, scale peeling off in sheets, necrosis of skin (gray areas), widespread bullae, severe mucositis (see Fig. 403-8) **DRESS:** facial edema
Other	Potentially life-threatening • Disseminated intravascular coagulation (see Fig. 403-9) Usually not immediately life-threatening • Neoplastic (e.g., lymphoma) • Inherited (e.g., periodic fever syndromes)	Widespread retiform purpura, including above the waist

*Not a single site, as in cellulitis or necrotizing fasciitis.

†More likely in immunocompromised patient.

AGEP = acute generalized exanthematous pustulosis; DRESS = drug reaction with eosinophilia and systemic symptoms (also referred to as DIHS = drug-induced hypersensitivity syndrome); HHV = human herpes virus; HIV = human immunodeficiency virus; SLE = systemic lupus erythematosus.

Adapted from Bolognia JL, Schaffer JV, Duncan KO, Ko CJ. *Dermatology Essentials*. Elsevier; 2014.

FIGURE 403-3. Disseminated varicella-zoster virus. Widespread, individual papules and vesicles, many with hemorrhage. Note the absence of coalescence into larger bullae.

FIGURE 403-4. Acute meningococcemia. Retiform purpura with irregular outline and grayish-red color. (Courtesy Kalman Watsky, MD. From Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology,* 3rd ed. Philadelphia: Saunders; 2012.)

FIGURE 403-5. Toxic shock syndrome. Acute erythema in a swim-trunk distribution can be an early sign of toxic shock syndrome. Similar erythema occurs on dorsal hands and feet. Peeling of the skin in these areas occurs 1 to 2 weeks later.

FIGURE 403-6. Mucormycosis. Angioinvasive organisms led to extensive microvascular occlusion, with skin findings of purpura, necrosis, and sloughing.

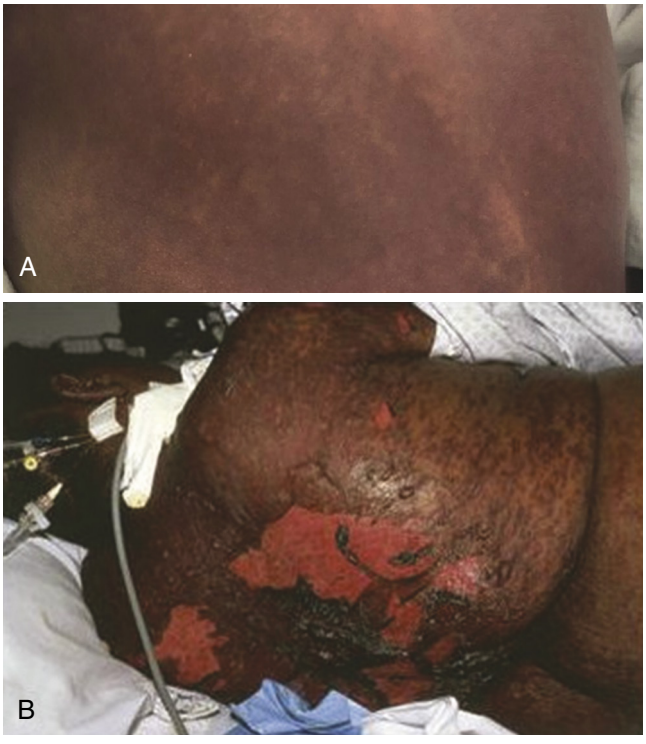

FIGURE 403-7. Toxic epidermal necrolysis. A, Early on, only erythema may be seen. **B,** Detachment of large sheets of necrolytic epidermis (>30% body surface area), leading to extensive areas of denuded skin. A few intact bullae are still present. (From Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology,* 3rd ed. Philadelphia: Saunders; 2012:328, Fig. 20.10A.)

FIGURE 403-8. Mucositis (Stevens-Johnson syndrome). Extensive erosive changes on lips and oral mucosa are highly suggestive of a severe drug eruption such as Stevens-Johnson syndrome or toxic epidermal necrolysis.

FIGURE 403-9. Disseminated intravascular coagulation. Noninflammatory (without underlying erythema) retiform purpura as well as hemorrhagic bullae in a patient with disseminated intravascular coagulation (DIC). (Courtesy Judit Stenn, MD. From Bolognia JL, Jorizzo JL, Schaffer JV. *Dermatology,* 3rd ed. Philadelphia: Saunders; 2012.)

FIGURE 403-10. Vesicles and bullae (bullous pemphigoid). Large bullae as well as smaller bullae and vesicles on a background of urticaria-like erythema.

FIGURE 403-11. Severe allergic contact dermatitis. Bullae and vesicles on a background of erythema. Severe cases such as this can be mistaken for the autoimmune disease bullous pemphigoid.

TABLE 403-9 APPROACH TO THE PATIENT WITH GENERALIZED PRURITUS AND NO OBVIOUS SKIN-SPECIFIC DISEASE

HISTORY
Complete history and review of systems • Consider risk factors for scabies (e.g., nursing home resident, close contact with recent diagnosis, symptoms in household contacts) • Ask about dermographism (exaggerated tendency to develop wheals with scratching of the skin—a type of physical urticaria), xerosis, irritants, occupational exposures • Review all medications (prescription,* OTC, supplements, illicit)
PHYSICAL EXAMINATION
Complete skin examination Lymph node examination
SCREENING LABORATORY TESTS
CBC with differential and platelets ESR and LDH TSH BUN/creatinine Liver function tests
ADDITIONAL EVALUATION (AS INDICATED BY AGE, HISTORY, COMORBID CONDITIONS, AND SCREENING TESTS)
Additional blood tests • Serum fasting glucose and Hgb A_{1c} • Serum calcium and phosphate levels • Albumin level • Ferritin, iron studies • Anti–tissue transglutaminase antibodies • Viral hepatitis screen • HIV testing Other tests • Chest radiograph • Age-appropriate cancer screening examinations • Stool exam for ova and parasites • Endoscopy

*Drug-induced pruritus: major culprits include calcium-channel blockers, proton pump inhibitors, narcotics, and amphetamines.

BUN = blood urea nitrogen; CBC = complete blood count; ESR = erythrocyte sedimentation rate; Hgb = hemoglobin; HIV = human immunodeficiency virus; LDH = lactate dehydrogenase; OTC = over-the-counter; TSH = thyroid-stimulating hormone.

Adapted from Bolognia JL, Schaffer JV, Duncan KO, Ko CJ. *Dermatology Essentials*. Elsevier; 2014.

pruritus and no signs of a specific skin disorder, a comprehensive diagnostic approach is indicated (Table 403-9)[12] to detect causes of pruritus as diverse as occult skin disease (scabies), medications (especially calcium-channel blockers, proton pump inhibitors, narcotics, and amphetamines), renal failure (Chapter 100),[13] cholestatic liver disease (Chapter 141),[14] hyperthyroidism (Chapter 207), myeloproliferative disorders (Chapter 152), parasitic infections, diabetes mellitus (Chapter 210), and celiac disease (Chapter 126). Anxiety and depression are often associated with chronic pruritus.[15]

TREATMENT

Treatment of pruritus can be tailored according to its probable cause. For primary dermatoses, such as eczema (Chapter 405), specific disease-related treatments will also reduce pruritis. For example, gabapentin is the preferred treatment for the pruritus of renal failure,[A1] bezafibrate is effective for the itch of cholestatic diseases,[A2] and ondansetron (4 mg intravenously) is effective for otherwise refractory morphine-induced pruritus.[A3] Itching from dry skin, such as eczema (Chapter 405), cholestatic jaundice (Chapter 141), hypothyroidism (Chapter 207), or myeloproliferative diseases (Chapter 152) may respond to over-the-counter emollients (Table 403-10). A mainstay of treatment of skin inflammation causing pruritus is topical corticosteroids or topical calcineurin inhibitors. Urticaria, which is an inflammatory disease of the skin with histamine release from mast cells in the dermis, can be treated with oral antihistamines.[16,A4] Other forms of pruritus may not respond directly to antihistamines (see Table 404-3), but antihistamines nevertheless may help the patient because of their sedative effects. For pruritus that originates in afferent nerves, capsaicin can be helpful over the long term because it depletes neural stimulatory peptides. Pruritus that is more centrally caused may respond to oral medications such as naltrexone or gabapentin, and mirtazapine may be helpful for patients in whom depression or anxiety play an important role.[17] For inflammatory skin disease as well as systemic causes of pruritus, ultraviolet light therapy also can be helpful.

TABLE 403-10 TREATMENT OF PRURITUS

TOPICAL AGENTS
Emollients
Eucerin (e.g, Skin Calming Crème), CeraVe (e.g., Itch Relief Moisturizing Cream), Aveeno (e.g. Eczema Therapy Moisturizing Cream) as needed daily
Corticosteroid ointment (corticosteroids should be discontinued following clinical response; medium- to high-potency steroids should not be used continuously for more than 2 weeks)
Low potency: hydrocortisone 2.5% cream, one to two times daily as needed
Medium potency: desoximetasone cream 0.05%, one to two times daily as needed
High potency: clobetasol cream 0.05%, one to two times daily as needed
Calcineurin inhibitors
Tacrolimus 0.03 and 0.1% ointment, one to two times daily as needed
Pimecrolimus 1% cream, one to two times daily as needed
Anesthetic agents (can be especially useful for neuropathic itch)
Capsaicin 0.025% cream, four times daily
Pramoxine 1%-hydrocortisone 2.5% lotion, cream, or ointment one to two times daily as needed
SYSTEMIC MEDICATIONS
Antihistamines (see Table 404-3)
Antidepressants
Mirtazapine 15 mg PO at bedtime
Opioids
Naltrexone 50 mg/day PO for cholestatic pruritus
Anticonvulsants
Gabapentin PO 300 mg three times/week after dialysis for pruritus in renal dialysis patients
Ultraviolet B radiation one to three times/week for six to eight exposures

PO = orally.

404 PRINCIPLES OF THERAPY OF SKIN DISEASES

VICTORIA P. WERTH AND APRIL W. ARMSTRONG

The goal of therapy is to improve a skin condition with the least toxic and most specific approach. Because many treatments or medications can be applied directly to the skin, the option for topical therapy is attractive for treating many dermatologic diseases. However, many diseases require systemic therapy, particularly when patients have widespread involvement of the skin or a disease that cannot be improved with topical therapy. Therapies work by improving barrier function, removing scale, altering inflammation in the skin, altering blood flow, providing antimicrobial effects, or affecting proliferating cells. Recent advances in the understanding of cutaneous biology have not been routinely accompanied by evidence-based documentation of the benefits of many specific therapies.

PRINCIPLES OF TOPICAL THERAPY

SOAKS AND DRESSINGS

Water or saline applied by soaks and wet dressings can be beneficial for many skin conditions, including ulcers, by promoting healing of the epidermis and débridement of crusts. Soaked gauze is applied to involved areas for 15 to 30 minutes several times per day, and care should be taken not to allow the gauze to dry and adhere. If adherence occurs, the gauze should be soaked before the dressing is removed. Use of strong antiseptic solutions, including hydrogen peroxide, is not recommended because of toxicity to cells. Whirlpool action can enhance débridement. When large areas of skin are involved, baths are a convenient way to treat the skin with medications that reduce itching and inflammation. The best time to apply moisturizers that help trap water in the upper layers of skin is immediately after a bath or shower.

Wet-to-dry dressings are rarely used, except when initial vigorous wound débridement is necessary. Continued use after wounds are débrided traumatizes wounds and delays healing. Moist wound healing, which is often ideal, can be accomplished with a topical antibiotic such as a combination of polymyxin B and bacitracin (Polypore) or mupirocin (Bactrian), gauze impregnated with petrolatum (Vaseline), or an occlusive hydrocolloid dressing. Little evidence indicates that débriding enzymes are beneficial. Compression with an Unna or multilayered boot, which includes an elastic dressing such as Coban, can decrease local edema and facilitate wound healing. Polysporin/petrolatum gauze or occlusive dressings are placed underneath, an approach that is helpful for chronic venous, diabetic, and pressure ulcers, as well as for acute wounds. Closed wet dressings, in which gauze is soaked and then covered with an impervious material, can help when maceration and heat retention are needed. Biologic dressings with skin substitutes or keratinocytes can be beneficial for wounds that are resistant to healing.[A1] Skin grafts also can facilitate healing of otherwise nonhealing wounds. Platelet-derived growth factor, which is approved for use on diabetic ulcers, can modestly improve wound healing.

TOPICAL MEDICATIONS

Topical medications mix an active drug with preservatives, emulsifying agents, and an appropriate base or vehicle. Systemic absorption varies among patients, sites, and vehicles. Topically applied drugs are absorbed more readily through inflamed, thin skin. The base can be any of the following: a *powder*, which promotes dryness and is used to reduce maceration in intertriginous areas; a *lotion*, which is a suspension of oil in water; *solutions*, which include water, alcohol, and propylene glycol, but not oil; *gels*, which are solid at room temperature but melt on contact with the skin; a *cream*, which is an emulsion of oil in water that leaves a thin oil coating as the water evaporates; an *ointment*, which combines oils, such as petrolatum (Vaseline), with small amounts of water and which is more occlusive and hence increases the absorption of medication but also results in a greasier appearance; a *paste*, which is a mixture of powder and ointment; *foam*, which enables rapid deposition of active drug on the skin surface after the body heat evaporates inert contents; or a *spray*. Lotions, solutions, and gels provide less penetration than ointments do, but they are especially useful for the treatment of hair-bearing areas such as the scalp, where greasiness is displeasing. Creams are less greasy than ointments and are useful for the face, groin, and intertriginous areas. Ointments are often more effective for dry, scaly conditions such as eczema and psoriasis and are helpful in areas that have thick skin, such as the palms and soles, but they should be avoided in infected or intertriginous areas.[1] The choice of base is determined by the skin condition and location. Impregnated tapes are another delivery method to provide occlusion and protect the skin from manipulation. Active drugs with different optimal pH can now be combined with specialized bases.

ANTI-INFLAMMATORY AGENTS

GLUCOCORTICOIDS

Topical glucocorticoids work because of their effects on vasoconstriction, proliferation, immunosuppression, and inflammation. Assays related to the ability to vasoconstrict and clinical trials of efficacy have allowed glucocorticoids to be divided into various classes based on potency (Table 404-1). These

404 PRINCIPLES OF THERAPY OF SKIN DISEASES

VICTORIA P. WERTH AND APRIL W. ARMSTRONG

The goal of therapy is to improve a skin condition with the least toxic and most specific approach. Because many treatments or medications can be applied directly to the skin, the option for topical therapy is attractive for treating many dermatologic diseases. However, many diseases require systemic therapy, particularly when patients have widespread involvement of the skin or a disease that cannot be improved with topical therapy. Therapies work by improving barrier function, removing scale, altering inflammation in the skin, altering blood flow, providing antimicrobial effects, or affecting proliferating cells. Recent advances in the understanding of cutaneous biology have not been routinely accompanied by evidence-based documentation of the benefits of many specific therapies.

PRINCIPLES OF TOPICAL THERAPY

SOAKS AND DRESSINGS

Water or saline applied by soaks and wet dressings can be beneficial for many skin conditions, including ulcers, by promoting healing of the epidermis and débridement of crusts. Soaked gauze is applied to involved areas for 15 to 30 minutes several times per day, and care should be taken not to allow the gauze to dry and adhere. If adherence occurs, the gauze should be soaked before the dressing is removed. Use of strong antiseptic solutions, including hydrogen peroxide, is not recommended because of toxicity to cells. Whirlpool action can enhance débridement. When large areas of skin are involved, baths are a convenient way to treat the skin with medications that reduce itching and inflammation. The best time to apply moisturizers that help trap water in the upper layers of skin is immediately after a bath or shower.

Wet-to-dry dressings are rarely used, except when initial vigorous wound débridement is necessary. Continued use after wounds are débrided traumatizes wounds and delays healing. Moist wound healing, which is often ideal, can be accomplished with a topical antibiotic such as a combination of polymyxin B and bacitracin (Polypore) or mupirocin (Bactrian), gauze impregnated with petrolatum (Vaseline), or an occlusive hydrocolloid dressing. Little evidence indicates that débriding enzymes are beneficial. Compression with an Unna or multilayered boot, which includes an elastic dressing such as Coban, can decrease local edema and facilitate wound healing. Polysporin/petrolatum gauze or occlusive dressings are placed underneath, an approach that is helpful for chronic venous, diabetic, and pressure ulcers, as well as for acute wounds. Closed wet dressings, in which gauze is soaked and then covered with an impervious material, can help when maceration and heat retention are needed. Biologic dressings with skin substitutes or keratinocytes can be beneficial for wounds that are resistant to healing.[A1] Skin grafts also can facilitate healing of otherwise nonhealing wounds. Platelet-derived growth factor, which is approved for use on diabetic ulcers, can modestly improve wound healing.

TOPICAL MEDICATIONS

Topical medications mix an active drug with preservatives, emulsifying agents, and an appropriate base or vehicle. Systemic absorption varies among patients, sites, and vehicles. Topically applied drugs are absorbed more readily through inflamed, thin skin. The base can be any of the following: a *powder*, which promotes dryness and is used to reduce maceration in intertriginous areas; a *lotion*, which is a suspension of oil in water; *solutions*, which include water, alcohol, and propylene glycol, but not oil; *gels*, which are solid at room temperature but melt on contact with the skin; a *cream*, which is an emulsion of oil in water that leaves a thin oil coating as the water evaporates; an *ointment*, which combines oils, such as petrolatum (Vaseline), with small amounts of water and which is more occlusive and hence increases the absorption of medication but also results in a greasier appearance; a *paste*, which is a mixture of powder and ointment; *foam*, which enables rapid deposition of active drug on the skin surface after the body heat evaporates inert contents; or a *spray*. Lotions, solutions, and gels provide less penetration than ointments do, but they are especially useful for the treatment of hair-bearing areas such as the scalp, where greasiness is displeasing. Creams are less greasy than ointments and are useful for the face, groin, and intertriginous areas. Ointments are often more effective for dry, scaly conditions such as eczema and psoriasis and are helpful in areas that have thick skin, such as the palms and soles, but they should be avoided in infected or intertriginous areas.[1] The choice of base is determined by the skin condition and location. Impregnated tapes are another delivery method to provide occlusion and protect the skin from manipulation. Active drugs with different optimal pH can now be combined with specialized bases.

ANTI-INFLAMMATORY AGENTS

GLUCOCORTICOIDS

Topical glucocorticoids work because of their effects on vasoconstriction, proliferation, immunosuppression, and inflammation. Assays related to the ability to vasoconstrict and clinical trials of efficacy have allowed glucocorticoids to be divided into various classes based on potency (Table 404-1). These

ABSTRACT

The goal of therapy is to improve a skin condition with the least toxic and most specific approach. Because many treatments or medications can be applied directly to the skin, the option for topical therapy is attractive for treating many dermatologic diseases. However, many patients require systemic therapy, particularly when they have widespread involvement of the skin or a disease that cannot be improved with topical therapy. Therapies work by improving barrier function, removing scale, altering inflammation in the skin, altering blood flow, providing antimicrobial effects, or affecting proliferating cells.

KEYWORDS

therapy
topical therapy
glucocorticoids
anti-inflammatory agents
antiviral therapy
immunomodulatory therapy

TABLE 404-1 RANKING OF SOME COMMONLY USED TOPICAL STEROIDS BY POTENCY

Super potency	Clobetasol propionate (Temovate ointment and cream), betamethasone dipropionate (Diprolene cream and ointment), diflorasone diacetate (Psorcon E ointment), halobetasol propionate (Ultravate ointment)
High potency	Amcinonide, mometasone furoate ointment, diflorasone diacetate (Florone ointment), halcinonide 0.1% cream, fluocinonide, desoximetasone, triamcinolone acetonide, diflorasone diacetate ointment and cream, betamethasone dipropionate (Diprosone), betamethasone benzoate and valerate
Medium potency	Fluticasone propionate; mometasone furoate cream; halcinonide 0.25% ointment; triamcinolone acetonide 0.1% cream and lotion; fluocinolone acetonide 0.05%, and 0.1% cream, 0.1% and 0.25% ointment, and 0.5% solution; hydrocortisone valerate 0.2% ointment and cream; alclometasone dipropionate 0.5% ointment; betamethasone dipropionate 0.5% lotion; hydrocortisone butyrate 0.1% cream; betamethasone benzoate 0.25% cream; betamethasone valerate 0.1% cream and 0.5% lotion; flumethasone pivalate 0.3% cream; desonide 0.5% cream
Low potency	Hydrocortisone 1% cream

TABLE 404-2 CLINICAL APPLICATION OF TOPICAL GLUCOCORTICOIDS

Super potency and high potency	Plaque and palmoplantar psoriasis, lichen planus, dyshidrotic eczema, lichen simplex chronicus, granuloma annulare, sarcoidosis
Medium potency	Dermatitis: allergic contact, atopic, neurodermatitis
Low potency	Intertrigo, pruritus ani, seborrheic dermatitis

medications are typically used twice per day. Side effects include atrophy of the skin, telangiectases, purpura, striae, local skin infections (e.g., folliculitis, tinea, and candidiasis), hypopigmentation, hypertrichosis, systemic adrenal suppression when these agents are used on as little as 20% of the skin's surface area, and glaucoma when they are used around the eye. Side effects are especially prevalent when fluorinated steroids are used on thin skin (e.g., face, groin, or scrotum), and prolonged use on the face can result in facial dermatitis, acne, and an eruption resembling acne rosacea that is often exacerbated when use of the steroid is terminated. Certain conditions are more responsive to steroids, and the potency of the steroid chosen must be based on the condition and its location (Table 404-2). The superpotent class I agents should be restricted to patients with severe dermatoses, and their use normally should not exceed 2 weeks. Patients who receive these potent agents require frequent follow-up and must be carefully evaluated for the need to continue strong topical steroids. Use of any fluorinated steroid on the face requires an exact diagnosis and should be limited in the extent of application and duration of use. Intralesional glucocorticoids can be injected into individual lesions to improve delivery of the medication, and this method is commonly used to treat patients with acne cysts, hypertrophic scars, keloids, alopecia areata, granuloma annulare, discoid and panniculitic lupus erythematosus (Chapter 245), psoriasis, and lichen simplex chronicus. Triamcinolone acetonide is most frequently used, followed by the longer-acting triamcinolone hexacetonide. It is important to use proper dilutions, such as 1 to 2.5 mg/mL on the face and 5 mg/mL elsewhere, to avoid local skin atrophy. Because these drugs vary widely in price and often require at least some out-of-pocket patient payments, physicians can help their patients by being knowledgeable about their prices.

Systemic glucocorticoids are used for acute and chronic conditions in dermatology, but they should be avoided, if possible, or minimized because of their well-known side effects (Chapter 28). Acute conditions that commonly require systemic steroids include severe contact dermatitis such as poison ivy, photodermatitis, severe atopic dermatitis, and acute urticaria. Many skin conditions such as psoriasis and eczema become exacerbated when use of the steroids is tapered, so steroids should be avoided when possible in these conditions. The dose of steroid must be individualized to the condition and its severity. Steroid-sparing drugs, such as immunosuppressive or immunomodulatory agents, can be used to minimize the long-term use of steroids for selected conditions.

NONSTEROIDAL ANTI-INFLAMMATORY AGENTS

Psoriasis Therapies

Tars and anthralin are less commonly used for psoriasis (Chapter 405) than are other agents. Tars had been most commonly used in conjunction with ultraviolet B (UVB) light. Tars also are used in shampoos and bath oils to treat seborrhea and psoriasis. Anthralin is a synthetic hydroxyanthrone that inhibits keratinocyte proliferation; it stains and can be irritating, but it can be an effective therapy (Chapter 405).

Calcipotriol

Calcipotriol is a vitamin D derivative that has antiproliferative and immunomodulatory effects on skin. Hypercalcemia can occur if more than 100 g/week is used, so this agent cannot be used for widespread disease. It is applied twice daily, can be irritating on thin skin, and takes 6 to 8 weeks to be effective.

Retinoids

The retinoids are a group of compounds that include vitamin A and its derivatives. Their effects are mediated through several different classes of receptors, and the receptor-drug complex has effects on other regulatory proteins that affect growth factors, oncogenes, keratins, or transglutaminases. Retinoids affect cell growth, differentiation, and morphogenesis; inhibit tumor promotion and malignant cell growth; have immunomodulatory effects; and alter cell cohesion.

Topical retinoids include all-*trans*-retinoic acid (tretinoin), which is approved for acne (Retin-A) and photoaging (Renova 0.05% cream) and is also useful for hyperpigmentation, steroid-induced atrophy, and early stretch marks.[1] Tretinoin is available as a cream (0.025%, 0.05%, 0.1%), a gel (0.01%, 0.025%), and a solution (0.05%). Adapalene (Differin 0.1% gel) and tazarotene (Tazorac) are used for acne (Chapter 406). Tazarotene is also used for psoriasis, often in combination with topical steroids to minimize irritation and chronic photodamage. Bexarotene (Targretin) 1% gel is used for the topical treatment of cutaneous lesions in patients who have refractory or persistent stage IA or IB cutaneous T-cell lymphoma. Topical retinoids can be irritating and frequently cause an exacerbation before improvement. However, they should be used regularly on lesion-prone skin to produce improvement. Moisturizers may be needed to minimize drying effects.

Systemic retinoids commonly used for the skin include isotretinoin, acitretin, and bexarotene (Targretin). They have many applications, but most frequently isotretinoin (Accutane) is used for cystic and conglobate acne, acitretin for severe psoriasis (especially the erythrodermic and pustular forms), and bexarotene for cutaneous T-cell lymphoma. Isotretinoin and acitretin also have been used to treat several forms of ichthyosis and lupus erythematosus and for the chemoprevention of skin cancers, particularly in immunosuppressed transplant recipients. The many side effects of systemic retinoids include teratogenicity, cheilitis, hair loss, headaches, hyperlipidemia, abnormal liver enzyme levels, vertebral hyperostosis, tendon and ligament calcification, osteoporosis, and central hypothyroidism with bexarotene. Pregnancy must be avoided, and the use of retinoids in women of childbearing age therefore requires careful monitoring. Treatment of acne is reserved for cases of cystic acne not responding to less toxic therapies; in this setting, a 4- to 5-month course of Accutane, 0.5 to 1 mg/kg/day, is curative in 85 to 90% of patients.

OTHER AGENTS

Brimonidine and Oxymetazoline Hydrochloride

Brimonidine gel is a selective α_2-adrenergic receptor agonist. Oxymetazoline hydrochloride is an α_1-adrenergic receptor agonist. Both have vasoconstrictive activity and are used topically for rosacea.[A2] Crisaborole is a boron-based phosphodiesterase 4 inhibitor that increases intracellular cyclic adenosine monophosphate (cAMP) levels. It is applied as an ointment to treat atopic dermatitis.

Antimalarial and Antiparasitic Drugs

Aminoquinolines include hydroxychloroquine, quinacrine, and chloroquine. These agents have inhibitory effects on pro-inflammatory cytokine production, DNA replication, and chemotaxis. They are useful in patients with connective tissue diseases, polymorphous light eruption, sarcoidosis (Chapter 83), porphyria cutanea tarda (Chapters 194 and 406), sclerosing conditions,

and vasculitis. Side effects include diarrhea, headache, irritability, psychosis, skin dyspigmentation, and, rarely, retinopathy. Retinopathy is rare if doses of hydroxychloroquine are ≤5 mg/kg/day actual body weight or ≤2.3 mg/day for chloroquine. Combinations of hydroxychloroquine or chloroquine with quinacrine are frequently helpful when a solitary agent is inadequate. The combination of hydroxychloroquine and chloroquine should not be used because of the additive risk for retinopathy. Ivermectin cream is a broad-spectrum antiparasitic agent used for rosacea.[A3]

Dapsone

Dapsone is a sulfone that inhibits the response of neutrophils and possibly eosinophils to chemotactic stimuli. It is useful for dermatitis herpetiformis (Chapter 406), cutaneous vasculitis (Chapter 407), pyoderma gangrenosum (Chapter 407), bullous lupus erythematosus (Chapter 245), Behçet disease (Chapter 249), and autoimmune bullous diseases (Chapter 406). Topical 5% gel is approved for use in acne. Systemic use can be associated with side effects that include hemolysis, methemoglobinemia, peripheral neuropathy, agranulocytosis, and, rarely, a hypersensitivity syndrome with hepatitis, fevers, and rash. The glucose-6-dehydrogenase level should be checked before starting the drug, and it is common for patients with a normal glucose-6-dehydrogenase level to experience a 2-g/dL decrease in hemoglobin after achieving therapeutic doses of 100 to 200 mg/day.

Thalidomide and Lenalidomide

Thalidomide and lenalidomide have potent anti-inflammatory effects via their effects on two transcription factors that bind to cereblon. It also modifies adhesion molecules on circulating leukocytes. Thalidomide is a serious teratogen, and patients must comply with strict birth control and monitoring. It is effective at a dose of 50 to 100 mg/day, with improvement beginning in 2 weeks and a full clinical response seen in 2 to 3 months in patients with severe cutaneous lupus erythematosus (Chapter 245), erythema nodosum leprosum (Chapter 405), aphthae, Behçet disease (Chapter 249), scleromyxedema, actinic prurigo, chronic graft-versus-host disease (Chapter 163), multiple myeloma (Chapter 173), and numerous other inflammatory dermatoses. Besides teratogenesis, the main side effects include peripheral neuropathy, constipation, sedation, and, rarely, amenorrhea.

Colchicine

Colchicine, usually at a dose of 0.6 mg twice daily, is used for leukocytoclastic vasculitis (Chapter 406) and Behçet disease, as well as some patients with epidermolysis bullosa acquisita. The main side effect of this low oral dose is diarrhea.

ANTIMICROBIAL AGENTS

ANTIBACTERIALS

Topical antibiotics are used to treat superficial skin diseases, such as acne and folliculitis, as well as skin wounds and ulcers. They may work by decreasing neutrophil chemotaxis and other anti-inflammatory mechanisms. Topical solutions, gels, pledgets, and ointments are available, depending on the agent, and antibiotics include erythromycin, clindamycin, tetracycline, and metronidazole.[2] Benzoyl peroxide also has antibacterial properties and is quite effective for mild-to-moderate acne, while also minimizing bacterial resistance when topical antibiotics are also used (Chapter 406). Bacitracin and Polysporin ointments are typically used for wounds, but they can cause contact hypersensitivity; neomycin should be avoided because of the high incidence of allergic reactions. Mupirocin is particularly effective against *Staphylococcus* and *Streptococcus* spp., and it can be used in the nose for carriers of staphylococci. Systemic antibiotics such as penicillins, cephalosporins, and erythromycin are used in patients with soft tissue infections such as impetigo, folliculitis, furuncles, carbuncles, cellulitis, ecthyma, erysipelas, postoperative wound infections, and necrotizing fasciitis. Tetracycline, doxycycline, and minocycline are used for acne,[3,4] rosacea, and perioral dermatitis. Fluoroquinolones such as ciprofloxacin are useful for the treatment of gram-negative soft tissue infections.

ANTIFUNGALS

Topical antifungal agents are used in patients with limited superficial fungal infections of the skin (Chapter 405). The numerous topical antifungal drugs available include the azoles (clotrimazole, econazole, ketoconazole, oxiconazole, and miconazole), which are available as creams and lotions applied once or twice daily. The creams tend to be more effective. Topical agents used for dermatophytes, but not *Candida*, are haloprogin and tolnaftate. The newer allylamine antifungals naftifine and terbinafine have fungicidal effects. Ciclopirox 8%, efinaconazole, and tavaborole are used topically to treat and prevent relapses of onychomycosis, but they are not as efficacious as systemic therapy (Chapter 409).[A4] Nystatin creams, oral suspensions, and vaginal tablets are effective for the treatment of *Candida* infections. The combination of antifungals with potent topical steroids such as betamethasone dipropionate is not advised because of increased side effects from the steroid and decreased efficacy of the antifungal as a result of the concomitant steroid.

Systemic antifungal agents include griseofulvin, terbinafine (allylamine), ketoconazole (imidazole), itraconazole, and fluconazole. These agents are used for extensive or severe superficial skin fungal infections (Chapter 405) caused by dermatophytes, *Candida*, or *Malassezia furfur* or for local infections not responsive to topical drugs, such as those found in the nails and scalp. Itraconazole and terbinafine are the only oral antifungals approved in the United States for the treatment of onychomycosis,[A5] and griseofulvin is the only oral agent approved for tinea capitis. Griseofulvin is best taken with a fatty meal to improve absorption and is the only antifungal drug not requiring regular monitoring of liver enzymes. Griseofulvin shows weak affinity for keratin, and thus it must be used for 18 months for onychomycosis of the toenails and 6 months for the fingernails to achieve even relatively poor cure rates. Terbinafine is the only fungicidal drug; the rest are fungistatic. The number of interactions with medications is lower with terbinafine than with the triazole antifungals and ketoconazole because terbinafine does not inhibit or induce hepatic isoenzyme cytochrome P (CYP3A4) (Chapter 25). However, terbinafine affects CYP2D6, another hepatic isoenzyme, so it is relatively contraindicated in patients who are taking cyclosporine or rifampin. Itraconazole and fluconazole have been used in pulse-dosing regimens for the treatment of onychomycosis. Fluconazole and terbinafine are not dependent on gastric acidity for optimal gastrointestinal absorption. Overall, the side effects of the systemic antifungal agents are similar and include headache and gastrointestinal symptoms (griseofulvin, terbinafine), nausea and vomiting (itraconazole, fluconazole, ketoconazole), hepatitis, and lupus-like syndromes (terbinafine).

ANTIVIRALS

Verrucae are treated with various destructive modalities, including 50 to 80% dichloroacetic acid and trichloroacetic acid solutions, podophyllin resin, and podofilox.[5] Immunosuppressed patients may benefit from treatment with intralesional cidofovir. Topical antiviral creams such as penciclovir and acyclovir do not significantly shorten the course of herpes simplex. Systemic antiviral drugs include acyclovir, valacyclovir, famciclovir, and foscarnet, which are used to treat primary and recurrent herpes simplex (Chapter 345) and herpes zoster (Chapter 346). These agents specifically block the function of herpesvirus DNA polymerase. Valacyclovir and famciclovir are available only orally in the United States, but their prolonged intracellular half-life allows less frequent dosing than with acyclovir. Patients with herpes zoster require higher doses than do patients with herpes simplex. Side effects include nausea and headaches. The varicella-zoster vaccine has significantly decreased the incidence of herpes zoster in individuals older than 50 years of age, and current recommendation is for vaccination after the age of 50 with Shingrix (Chapter 15). If possible, it should be administered before starting oral immunosuppressive agents.

ANTIPARASITICS

Topical antiparasitic medications are used to treat pediculosis capitis, pediculosis pubis, and scabies. In addition, topical metronidazole has anti-inflammatory properties and is used to treat rosacea. For pediculosis and scabies, clothing and bedding must be washed and all family members must be treated. Effective treatment includes 1% γ-benzene hexachloride (lindane), a chlorinated hydrocarbon pesticide that should not be used on young children or on pregnant or lactating women. It is ineffective against nits and thus must be reapplied after 1 week. Permethrin 5% cream (Elimite) for scabies or 1% cream rinse is particularly effective for head lice and requires just one application; 10% crotamiton (Eurax) and 5% topical sulfur ointments are less effective. Malathion is a moderately toxic organophosphate insecticide, but it must be applied overnight to treat lice. Pyrethrins (RID, Nix) are best used twice, 1 week apart, to treat head lice and nits.

ANTIPRURITIC OR ANESTHETIC AGENTS

TOPICAL ANALGESICS

Capsaicin, an active ingredient of cayenne peppers and other plants of the genus *Capsicum*, is used for postherpetic neuralgia and other painful nerve-related

TABLE 404-3 OVERVIEW OF ANTIHISTAMINES

ANTIHISTAMINE GROUP	GENERIC NAME	AVERAGE ORAL ADULT DOSES
FIRST-GENERATION H_1-TYPE ANTIHISTAMINES		
Alkylamine	Brompheniramine (Dimetapp)	4 mg q4-6h
	Chlorpheniramine (Chlor-Trimeton)	4 mg q4-6h (short acting); 8-12 mg q8-12h (long acting)
Amino alkyl ether (ethanolamine)	Clemastine fumarate	1.34 mg bid or 2.68 mg qd-tid
	Diphenhydramine (Benadryl)	25-50 mg q4-6h
Ethylenediamine	Pyrilamine (Triaminic)	30 mg bid
Phenothiazine	Promethazine (Phenergan)	10-12.5 mg qid
	Trimeprazine (Temaril)	2.5 mg q6h
Piperidine	Azatadine	1-2 mg q8-12h
	Cyproheptadine	4 mg q8h
	Diphenylpyraline	2 mg tid-qid
Piperazine	Hydroxyzine (Atarax)	25-100 mg tid-qid
SECOND-GENERATION H_1-TYPE ANTIHISTAMINES		
Alkylamine	Acrivastine (combined with pseudoephedrine in allergy medication)	8 mg qid
Piperidine	Astemizole (Hismanal)	10 mg qd
	Loratadine (Claritin)	10 mg qd
	Fexofenadine (Allegra)	60 mg bid or 180 mg qd
Piperazine	Cetirizine (Zyrtec)	5-10 mg/day
H_2-TYPE ANTIHISTAMINES		
	Cimetidine (Tagamet)	400 mg bid
	Ranitidine (Zantac)	150 mg bid
	Famotidine	10 mg bid
	Nizatidine	300 mg hs
H_1- AND H_2-TYPE ANTIHISTAMINES		
	Doxepin (Sinequan)	10-25 mg hs

bid = twice daily; hs = at bedtime; qd = once daily; qid = four times daily; tid = three times daily.

conditions. It causes excitation of neural afferent C fibers and reduces substance P levels. Capsaicin causes a burning sensation and is applied four or five times daily for 5 to 6 weeks. Eutectic mixture of local anesthetic (EMLA) is a mixture of lidocaine and prilocaine that is used under occlusion to induce cutaneous anesthesia before a procedure. Lidocaine can be used as a topical anesthetic, but benzocaine should be avoided because it is a sensitizer.

ANTIPRURITIC AGENTS

Doxepin 5% cream is used for localized pruritus. Menthol is a cyclic terpene plant alcohol used for non–histamine-related itching. Pramoxine hydrochloride is a topical anesthetic used for mild-to-moderate itching. Oral antihistamines play an important role in controlling pruritus in many skin conditions (Table 404-3), especially those mediated by histamine, such as urticaria, angioedema, and urticaria pigmentosa. H_1-receptor antihistamines are the cornerstones of routine therapy. The sedating and anticholinergic properties of many H_1-receptor antihistamines probably account for some of their efficacy. Compared with the first-generation H_1-receptor antihistamines, second-generation H_1-receptor antihistamines are less sedating and therefore are now more commonly used as among the first-line agents.[A6] If an agent from one group of H_1-receptor antihistamines is ineffective at one dose, consider dose-escalating that agent. If dose escalation fails, an agent from a different class should be administered or combined. The combination of two different H_1-receptor antihistamines can be used when a solitary agent does not work; in particular, use of a sedating antihistamine at night and a second-generation antihistamine during the day can be helpful. The skin contains both H_1- and H_2-receptors, and occasionally combining H_1- and H_2-receptor antagonists can be beneficial. For example, first-generation agents (e.g., hydroxyzine, 10 to 25 mg every 6 hours) can be started at low doses and increased as tolerated, and regular continuous dosing is recommended. The tricyclic antidepressant doxepin, normally started at 10 to 25 mg at bedtime, has both anti–H_1- and H_2-receptor activity, but it interacts with drugs metabolized by the CYP-450 pathway. Side effects of commonly used first-generation antihistamines include sedation, dry mouth, blurred vision, constipation, and urinary retention, and lower doses may be required in elderly patients. The recommended dose for second-generation antihistamines (e.g., fexofenadine, 60 mg twice daily) should not be exceeded. Newer antipruritic agents target interleukins 4, 13, and 31 (e.g., dupilumab for eczema; Chapter 405), immunoglobulin E (e.g., omalizumab for urticaria; Chapter 407), Janus kinase inhibitors (e.g., abrocitinib for atopic dermatitis),[A7] and phosphodiesterase inhibitors.[6]

AGENTS THAT IMPROVE SURFACE FUNCTIONS (LUBRICATION, SCALE)

MOISTURIZERS

Moisturizers improve skin by diminishing scale and increasing water content. They usually contain mixtures of water and fatty substances such as petrolatum, lanolin, lanolin derivatives, and fatty alcohols. Greasy moisturizers tend to function better, but they are less acceptable cosmetically.

KERATOLYTICS

α-Hydroxy acids (lactic acid, glycolic acid, citric acid, glucuronic acid, pyruvic acid) are extremely effective keratolytics. They are helpful in treating disorders of keratinization and photoaging, as well as acne. Propylene glycol, used in 40 to 60% aqueous solutions, can decrease scaling. Salicylic acid, which works by decreasing keratinocyte adhesion and hydrating keratins, is used in a range of concentrations with many different bases to remove scale, to soften the stratum corneum, or as destructive therapy to remove warts and calluses. Urea is used in varying concentrations to treat scaling.

IMMUNE THERAPIES

HORMONAL THERAPIES

Systemic therapies to modulate androgen production can be beneficial in patients with acne and hidradenitis suppurativa. Such treatments for moderate acne include spironolactone and, in women, U.S. Food and Drug Administration (FDA)–approved combination oral contraceptives, such as Ortho Tri-Cyclen (norgestimate and ethinyl estradiol), Estrostep (norethindrone acetate and ethinyl estradiol), and Yaz (drospirenone and ethinyl estradiol), as they would be prescribed for contraception (Chapter 220).

IMMUNOSUPPRESSIVE AGENTS

Topical cytotoxic drugs include 5-fluorouracil, mechlorethamine (nitrogen mustard), carmustine (BCNU), bleomycin, and the calcineurin inhibitors tacrolimus and pimecrolimus. Topical 5-fluorouracil interferes with pyrimidine metabolism and action and blocks DNA synthesis. It is used to treat actinic keratosis, superficial basal cell cancer, Bowen disease, bowenoid papulosis, actinic cheilitis, and warts. Topical use does not cause systemic toxicity, but expected side effects include local irritation, erythema, and pain. Nitrogen mustard and BCNU, which have alkylating agents that inhibit DNA, RNA, and protein synthesis, are used to treat cutaneous T-cell lymphoma (Chapter 171); they can cause cutaneous reactions and myelosuppression, and nitrogen mustard commonly causes a cutaneous hypersensitivity reaction.

Intralesional bleomycin, which disrupts DNA synthesis, has been used to treat warts. Topical tacrolimus (Prograf) and pimecrolimus, immunosuppressive macrolides that act on T lymphocytes to inhibit interleukin-2 (IL-2) transcription, are used for atopic dermatitis, allergic contact dermatitis, psoriasis, and several other inflammatory skin conditions. They frequently cause a burning sensation in the skin; although systemic absorption is minimal, ongoing studies are assessing whether the risk for cancer is increased by their topical use. Systemic immunosuppressives such as methotrexate, azathioprine, thioguanine, hydroxyurea, mycophenolate (CellCept), cyclophosphamide, chlorambucil, rapamycin, and cyclosporine are used for numerous inflammatory or immunologically mediated skin conditions, particularly for widespread psoriasis (Chapter 405) and as glucocorticoid-sparing agents for autoimmune blistering diseases.

IMMUNOMODULATORY THERAPIES

Imiquimod, available as a 5% cream, is an imidazoquinolinamine that has antitumor and antiviral activity. It induces local production of interferon-γ and is used to treat warts and superficial skin cancers. Topical 3% diclofenac in hyaluronic acid, which blocks the induced cyclooxygenase-2 found in precancerous lesions, is approved to treat actinic keratosis. Many systemic immunomodulatory drugs are currently used in dermatology. These include interferons and tumor necrosis factor–α (TNF-α) inhibitors such as etanercept, adalimumab, and infliximab (Remicade). Anti-IL-12/23 therapy, anti-IL-17 therapy, anti-IL-17 receptor therapy, and IL-23 inhibitors are effective for psoriasis (Chapter 405).[A8]

Anti-CD20 antibodies have been effective in the treatment of autoimmune skin-blistering diseases, and rituximab is FDA approved for pemphigus vulgaris.[A9] Intravenous immunoglobulin, which is used to treat certain autoimmune skin diseases, including pemphigus vulgaris, cicatricial pemphigoid, and dermatomyositis, probably works through Fc receptor modulation and anti-idiotype interactions.

Interferon alfa-2b is used both intralesionally and subcutaneously to treat genital warts, high-risk melanoma, Kaposi sarcoma, hemangiomas, cutaneous T-cell lymphoma, keloids, Behçet disease, and cryoglobulinemia (Chapter 173), and perhaps basal cell and squamous cell carcinoma. Total interferon doses are generally 3 million IU or less per session, and systemic doses are usually administered 3 days per week. Side effects include flulike symptoms, leukopenia, anemia, and hepatitis. Denileukin diftitox is a fusion protein consisting of a fragment of diphtheria toxin genetically fused to IL-2. It targets IL-2 receptors on the surface of malignant cells and is approved for use in patients with resistant or recurrent cutaneous T-cell lymphoma.

Histone deacetylase inhibition increases acetylation of lysine residues that form the octomeric histone core of chromatin, thereby decreasing the ability of the histones to bind to DNA. This decreased binding allows chromatin expansion, permitting transcription of the tumor suppressor genes. However, histone deacetylase inhibitors affect acetylation globally and may have wider effects on various cellular functions. Two inhibitors (vorinostat and romidepsin) are approved by the FDA for use in patients with cutaneous T-cell lymphoma.

Extracorporeal photochemotherapy (photopheresis), which combines 8-methoxypsoralen and ultraviolet A (UVA) irradiation of lymphocytes, is used for Sézary syndrome, the leukemic form of cutaneous T-cell lymphoma (Chapter 171). Plasmapheresis, used in combination with other immunosuppressive therapies, can remove autoantibodies and immune complexes in patients in whom autoimmune disease or cryoglobulinemia is resistant to other therapies.

TREATMENT FOR SKIN CANCERS (SEE CHAPTER 188)

PHOTOTHERAPY AND LASER

Ultraviolet treatments are given with different wavelengths, depending on the condition and the response to treatment. Currently, clinicians use broad-band UVB (290 to 320 nm), narrow-band 311-nm UVB, PUVA (psoralen with 320- to 400-nm UVA), and UVA1 (340 to 400 nm). Both forms of UVB and PUVA are used for psoriasis and vitiligo, but other conditions such as nummular and atopic dermatitis, pruritus resulting from uremia, and cutaneous T-cell lymphoma are treated in this way. Because PUVA is associated with increased risk for skin cancers, including melanoma, UVB is generally preferred to treat psoriasis. High-dose UVA1 is used, mainly in Europe, to treat atopic dermatitis, localized scleroderma, and mastocytosis. The risks related to long-term UVA therapy are currently unknown, but photoaging is associated with UVA, and there have been reports of an increase in melanoma associated with use of suntanning beds, in which much of the exposure is to UVA. Laser therapy is used to treat vascular lesions such as port-wine stains, tattoos, psoriasis, benign skin tumors, and photodamage, as well as to remove hair. Photodynamic therapy involves activation of a photosensitizer by illumination with visible light, which leads to photochemical tissue destruction or immunomodulation. Photodynamic therapy can be used to treat actinic keratosis, Bowen disease, and superficial basal cell carcinoma by causing selective tissue necrosis and tumor destruction. Fractional lasers have been successfully used for treatment of actinic keratoses, photodamage, and scars.

DERMATOLOGIC SURGERY

Although approaches such as desiccation and curettage can be used for some skin tumors, others require excisional surgery or Mohs microscopic controlled surgery to ensure complete removal of lesions. If the tumors are recurrent, of a pathologic type that increases the likelihood for recurrence, or large and requiring clearance of the tumor before repair, the Mohs approach can provide rapid documentation of full removal while sparing as much normal tissue as possible. After the margins have been cleared of tumor, flaps and grafts can be used immediately for repair of the resultant defects.

Patients with extensive actinic damage resulting in either large numbers of actinic keratoses or photodamage can be treated with various ablative approaches that use either chemical peels or laser resurfacing with the carbon dioxide laser. Chemical peels can be performed at different depths and intensities, and agents can include glycolic acid, acetic acid, or even phenol. Lasers used to remove sun-induced lentigines include Q-switched lasers such as the neodymium:yttrium-aluminum-garnet, ruby, and alexandrite lasers. Many patients seek treatment of wrinkles with soft tissue augmentation that uses human-derived collagen and hyaluronic acid or with a muscle relaxer, botulinum type A exotoxin.

Hair transplants are a surgical approach to the problem of hair loss. The process includes harvesting hair grafts from the posterior of the scalp and placing the grafts in areas of alopecia.

SUNSCREEN

Transparent sunscreens, which absorb photons of light, are rated by the sun protection factor (SPF), which is determined by the ratio of ultraviolet exposure needed to cause erythema in protected versus unprotected skin. Most sunscreens work in the UVB range or shorter UVA wavelengths. Examples of UVB-absorptive compounds include aminobenzoates, cinnamates, salicylates, and benzophenones. Short-wavelength UVA-absorptive compounds include benzophenones and anthranilates. The best UVA blocking agent in the United States is avobenzone (Parsol 1789), which can be combined with UVB screens. Some sunscreens are water resistant or waterproof, as determined by the substantivity of the sunscreen, and these agents provide continued protection after sweating or swimming. Sunscreens can cause irritation and, rarely, contact allergic reactions. Physical sunscreens, such as zinc oxide and titanium dioxide, reflect light from the skin and include newer micronized reflecting powders that provide broad-spectrum (UVB and UVA) protection. Sunscreens decrease skin cancers and photodamage without compromising the synthesis of vitamin D or adversely affecting bone mineral density.[7] Although some active ingredients in sunscreen are absorbed into the systemic circulation, there is currently no evidence that such components represent a health hazard.[8,9] UVB is partially reflected by clothing, and sun-protective clothing can provide substantial protection (Solumbra, SPF of 30).

Visible light can cause redness in lighter-skinned individuals and pigmentation in darker-skinned individuals. Tinted sunscreens, which contain iron oxides and pigmentary titanium dioxide, protect against visible light[10] and are especially useful in patients with porphyria cutanea tarda and erythropoietic porphyria (Chapter 194).

COSMETICS: CAMOUFLAGE, BLEACHING, AND HAIR LOSS

Patients with numerous skin conditions benefit from camouflage cosmetics, which can also cause contact hypersensitivity. Products such as Dermablend can be blended to match skin colors, are thicker, can cover disfiguring lesions, and can be fixed with powder. Hydroquinones, topical retinoic acid, and azelaic acid (inhibits tyrosinase) are used to treat hyperpigmented conditions such as melasma and lentigines; these agents can be irritating and cause dyspigmentation. Topical minoxidil 2% (available over the counter) and 5% solutions are used for androgenic alopecia and alopecia areata. Finasteride, a 5α-reductase inhibitor, is effective in men with androgenic alopecia.

405 ECZEMAS, PHOTODERMATOSES, PAPULOSQUAMOUS (INCLUDING FUNGAL) DISEASES, AND FIGURATE ERYTHEMAS

HENRY W. LIM AND JOEL M. GELFAND

ECZEMA

The more commonly encountered eczemas (Table 405-1) share similar histologic characteristics. They have edema within the epidermis (spongiosis) and infiltration with lymphocytes and macrophages in the superficial dermis.

NUMMULAR DERMATITIS

Nummular dermatitis occurs most frequently in patients who are in their 50s to 60s. Both sexes are affected, and it is most frequently seen in the winter. The condition tends to be more frequent and severe among East Asians. The pathogenesis is unclear, although xerosis plays a significant role.

Patients present with pruritic, coin-shaped, erythematous patches with some scales and occasionally with pinhead-sized vesicles (Figs. 405-1 and 405-2). Lesions may be excoriated and lichenified (i.e., thickened skin with accentuation of skin markings). Legs and arms are commonly affected, and the trunk is less frequently involved; facial involvement is uncommon. All patients should be educated about the use of emollients and moisturizing soaps, and avoidance of long, hot showers. Topical corticosteroid ointments (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 weeks) are helpful for active lesions, and oral antihistamines (e.g., hydroxyzine 25 to 50 mg at bedtime) are useful for sedative effects when the patient's sleep is disturbed by pruritus. In severe cases, narrowband ultraviolet B (NB-UVB) phototherapy, and/or a short course of oral corticosteroids (prednisone, 0.5 to 1 mg/kg/day, with a maximal dose of 60 mg/day, for 1 to 2 weeks, then taper in 10 to 14 days) are beneficial. Some patients may require topical or oral antibiotics against *Staphylococcus aureus* if lesions become infected.

DYSHIDROSIS

Dyshidrosis manifests as pruritic, deep-seated, pinhead-sized vesicles, most commonly along the sides of the fingers (Figs. 405-3 and 405-4). Other features include xerosis, scaliness, and fissures. In severe cases, palms and soles also may be involved. Dyshidrosis is seen in individuals who wash their hands frequently, such as food industry workers, mothers of young infants, and increasingly in the general public during the severe acute respiratory syndrome coronavirus 2 pandemic. Treatment follows a sequential order: (1) replacing soap-and-water handwashing with hand sanitizers, (2) liberal use of emollients, and (3) topical corticosteroid ointments (e.g., fluocinonide ointment, 0.05% twice daily for 2 weeks). In some patients, a short course of oral prednisone (starting at 40 mg orally daily and tapering over 2 weeks) or longer term treatment with immune-suppressing medications (e.g., cyclosporine, 3 to 5 mg/kg daily for up to 12 months) may be needed.

ATOPIC DERMATITIS

Atopic dermatitis is most commonly seen among young children but may persist into adulthood or even begin in adulthood.[1] The prevalence has been estimated at between 15 and 23%.[2] Patients usually present with xerosis, erythematous scaly patches, small vesicles, excoriations, crusting, and, not infrequently, impetiginization (Fig. 405-5). In dark-skinned patients, a papular variant is commonly seen (Fig. 405-6). With chronic scratching and rubbing, hyperpigmentation and lichenification occur. Commonly affected sites include the periorbital area and flexor areas such as the neck, antecubital fossa, and popliteal fossa. In severe cases, the entire skin surface may be involved. Diagnosis is made by the typical morphology, the distribution of lesions, and family and personal history of atopy. The therapeutic ladder consists of (1) emollients; (2) topical corticosteroid ointments (e.g., triamcinolone ointment, 0.1% twice daily for 2 to 4 weeks), or topical calcineurin inhibitors (tacrolimus ointment,

ABSTRACT

Eczemas, photodermatoses, papulosquamous (including fungal) diseases, and figurate erythema have the common morphology of erythema, scaliness, papules, and vesicles. However, the pathophysiology, histology, and management are distinct for each of these diseases.

KEYWORDS

eczema
photodermatoses
lichen planus
tinea
mycosis fungoides

FIGURE 405-4. Dyshidrosis. Deep-seated vesicles and scaliness on fingers.

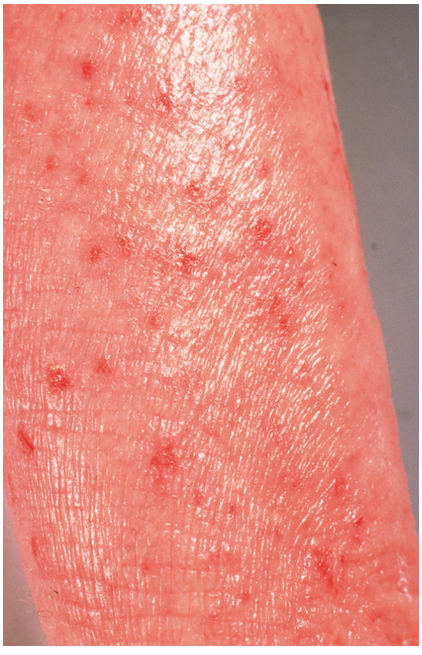

FIGURE 405-5. Atopic dermatitis. Note the erythema, excoriation, and lichenification.

0.1%, or pimecrolimus cream, 1% twice daily); (3) oral antihistamines (same dose range as nummular dermatitis); and (4) NB-UVB phototherapy.[3] Newer options for poorly responsive disease include crisaborole (a phosphodiesterase 4 inhibitor) 2% ointment applied twice daily,[A1] ruxolitinib (Janus kinase inhibitor) cream 1.5% twice daily, dupilumab (an interleukin-4 [IL-4] receptor α-antagonist) at 300 mg subcutaneously every other week,[A2,A3] tralokinumab (an IL-13 receptor blocker at 300 mg subcutaneously every other week to every 4 weeks)[A4], and two oral Janus kinase inhibitors (abrocitinib at 100 to 200 mg daily,[A5] and upadacitinib at 15 or 30 mg daily[A6]) are newer therapies especially for refractory disease.[A7] Cognitive behavioral therapy, even delivered over the internet, is also effective.[A8] Other traditional systemic treatments include oral prednisone (0.5 to 1 mg/kg/day), cyclosporine (3 to 5 mg/kg/day), and mycophenolate mofetil (1 to 2 g/day).

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a common condition that presents as erythematous patches with fine, greasy-appearing scales on the malar area, midforehead, midchest, and scalp (Fig. 405-7). In dark-skinned individuals, lesions may be hypopigmented (Fig. 405-8). The pathogenesis is unknown, although *Malassezia furfur* is believed to play a role. Lesions are common and more inflammatory in patients with human immunodeficiency virus (HIV) infection (Chapter 359) and may overlap with psoriasis. The diagnosis is made clinically. Topical corticosteroids (e.g., hydrocortisone cream 2.5%, twice daily for 1 to 2 weeks for facial lesions, fluocinolone acetonide 0.01% solution, gel, or ointment [depending on the patient's preference], twice daily for 3 to 4 weeks for the scalp) can rapidly reduce the inflammation; then topical ketoconazole cream, 2% twice daily, as needed (or shampoo 2% daily or every other day for the scalp), is safe for long-term treatment.[4]

FIGURE 405-7. Seborrheic dermatitis presenting as erythematous patches and plaques with fine scales on the malar area of an HIV-positive patient.

FIGURE 405-8. Seborrheic dermatitis. Hypopigmentation with fine scales on the forehead and scalp.

ALLERGIC CONTACT DERMATITIS AND IRRITANT CONTACT DERMATITIS

Allergic contact dermatitis is a delayed (occurring 24 to 48 hours after exposure) hypersensitivity response to external allergens,[5] whereas irritant contact dermatitis is a nonspecific toxic response to contact irritants. In both conditions, lesions occur in the exposed area. In severe cases, however, nonexposed areas may be involved, albeit less intensely. Allergic contact dermatitis presents with erythematous pruritic papules and vesicles in a pattern resembling the linear patches from poison ivy. Lesions resolve with fine scales. Postinflammatory hyperpigmentation may be observed. Histologically, epidermal edema and dermal histiocytic infiltrates are observed. The morphology of irritant contact dermatitis is similar to that of allergic contact dermatitis. However, irritant contact dermatitis is usually associated with a burning sensation rather than with pruritus. Postinflammatory hyperpigmentation is frequently observed. Histologic changes consist of necrotic keratinocytes, epidermal necrosis, and neutrophilic infiltrates. Management includes identification, which may require extensive patch testing, and removal of the offending agent, as well as symptomatic treatments such as topical corticosteroids and oral antihistamines.

PHOTODERMATOSES

Photodermatoses are cutaneous eruptions secondary to exposure to sunlight (Table 405-2). By convention, electromagnetic radiation in the ultraviolet (UV) region is divided into UVC (200 to 290 nm), UVB (290 to 320 nm), UVA-2 (320 to 340 nm), and UVA-1 (340 to 400 nm). Visible light extends from 400 to 700 nm. Because UVC emitted by the sun is absorbed by ozone in the stratosphere, UVC does not reach the earth's surface but is of medical interest as it is used for its germicidal effects (Chapter 18). UVB, UVA, and, less frequently, visible light are the relevant spectra in photodermatoses.

POLYMORPHIC LIGHT ERUPTION

Polymorphic light eruption is the most common immunologically mediated photodermatosis, occurring in 10 to 20% of the general population. It usually is seen in young adults, has a slight female predominance, and has been reported worldwide. Affected individuals are less susceptible to cutaneous photoimmunosuppression and hence have an enhanced response to UV-induced neoantigens in the skin. Lesions usually occur in early spring, within a few hours of exposure to sunlight. The lesions are mildly pruritic and manifest as pinhead papules (common among dark-skinned patients), papules, papulovesicles, or, less commonly, vesicles (Fig. 405-9). They persist for several days and resolve spontaneously. The condition tends to improve as the sunny season progresses, a phenomenon known as hardening.

The course is episodic but also chronic; only 11% of patients have complete resolution of the disease in 16 years and 24% in 32 years. Diagnosis is based on the typical history and morphology of the lesion. When lesions occur primarily on the face, a diagnosis of lupus must be excluded. Management consists of sun avoidance and the use of broad-spectrum sunscreens that cover both UVB and UVA with sun protection factor (SPF) of at least 30, topical corticosteroids, and oral antihistamines. In severe cases, desensitization treatment using NB-UVB is beneficial. Desensitization is usually performed in early spring by exposing patients to increasing doses of NB-UVB three times weekly for 15 to 20 treatments.

CHRONIC ACTINIC DERMATITIS

Chronic actinic dermatitis is a photodermatosis that occurs most commonly in men in their 60s and 70s. It occurs in patients of all ethnic groups, but in the United States it is more commonly seen in dark-skinned individuals. It is seen in 5 to 17% of patients referred for evaluation of photosensitivity. This condition has been postulated to represent a delayed hypersensitivity response to an unidentified antigen.

Patients present with lichenified plaques on sun-exposed areas (Figs. 405-10 and 405-11). Typically, sun-protected areas, such as the postauricular area, the area underneath the chin, the area above the eyes, and the trunk, are spared. Histologically, a dermal lymphohistiocytic infiltrate is seen, and atypical mononuclear cells may be observed. On phototesting, patients have increased sensitivity to UVB, UVA, and, less commonly, to visible light. In a study of

FIGURE 405-9. Polymorphic light eruption. Erythematous papules a few hours after exposure to sunlight.

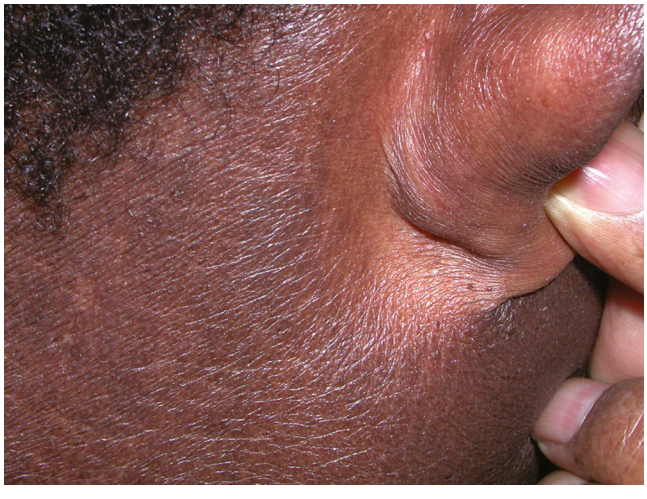

FIGURE 405-11. Hyperpigmentation and lichenification in a patient with chronic actinic dermatitis. Note sparing of the sun-protected postauricular area.

178 cases, 10% resolved in 5 years and 50% in 15 years. An association with HIV infection (Chapter 359) has been reported.

The diagnosis is based on the patient's history, morphology, and distribution of the lesions. It is confirmed by phototesting.

Management is challenging. Rigorous photoprotection is a must: staying in the shade, using broad-spectrum sunscreens with SPF 50 or more, and wearing photoprotective clothing, sunglasses, and a wide-brimmed hat. Other treatment modalities, in approximate sequential order, are topical corticosteroids (fluocinonide ointment 0.05% twice daily), tacrolimus ointment (0.1% twice daily), oral mycophenolate mofetil (1 to 2 g/day), oral cyclosporine (3 to 5 mg/kg/day), and azathioprine (up to 2 to 2.5 mg/kg/day). Treatment with oral corticosteroids (e.g., prednisone, 1 mg/kg/day) may be needed for acute flare. In recalcitrant cases, low-dose PUVA or NB-UVB in conjunction with oral corticosteroids may be helpful, and dupilumab (300 mg subcutaneously every other week) has been reported to be successful in some patients.[6]

PHOTOTOXICITY AND PHOTOALLERGY

The terms *phototoxicity* and *photoallergy* refer to the development of skin lesions after combined exposure to an oral or topical photosensitizer and electromagnetic radiation. Phototoxicity is a nonspecific cutaneous toxic reaction, whereas photoallergy is a delayed hypersensitivity response. For all photosensitizers, the action spectrum for both lies in the UVA range (Table 405-3).

CUTANEOUS PORPHYRIAS

The most common cutaneous porphyria is porphyria cutanea tarda, in which patients present with skin fragility and blisters on sun-exposed areas, most commonly the dorsum of the hands and the forearms (Fig. 405-12; Chapter 194).[7] Patients may have periorbital hypertrichosis and mottled hyper- and hypopigmentation, and infrequently, sclerodermoid skin changes. Sclerodermoid skin changes can occur in both sun-exposed and sun-protected areas. The defective enzyme is uroporphyrinogen decarboxylase. It is associated with excessive alcohol intake, exposure to estrogens, hepatitis C infection (Chapter 135), HIV infection (Chapter 359), and hemochromatosis (Chapter 196). Patients invariably have an elevated level of ferritin and frequently have elevated liver enzyme values.

TABLE 405-3 PHOTOTOXICITY AND PHOTOALLERGY

FEATURES	PHOTOTOXICITY	PHOTOALLERGY
Lesions after first exposure	Yes	No
Onset	Minutes after sun exposure	Delayed (24-48 hr after sun exposure)
Common offending agents	Systemic medications	Sunscreen agents
Morphology	Vesicles, bulla, hyperpigmentation	Eczematous (erythema, scaliness)
Management	Symptomatic (topical corticosteroids, antihistamine)	Removal of the offending agent

FIGURE 405-12. Erosion, crusting, and vesicles on the dorsum of the hand of a patient with porphyria cutanea tarda.

Laboratory findings are characterized by elevated levels of 8-, 7-, 6-, 5-, and 4-carboxyl porphyrins in the serum and urine, and isocoproporphyrin in feces (Chapter 194). Management consists of avoidance of precipitating factors (alcohol, iron-containing vitamins, estrogen-containing birth control pills) and weekly phlebotomy. In patients who are anemic, low-dose hydroxychloroquine (200 mg/week) is beneficial. In patients with concurrent chronic hepatitis C (Chapter 135), effective antiviral treatment of the hepatitis C can reduce the relapse rate of skin symptoms.

The second most common, albeit uncommon, porphyria is erythropoietic protoporphyria (Chapter 194). Defective ferrochelatase results in elevated protoporphyrin levels in erythrocytes and serum. Patients present with a life-long history of a stinging and deep-seated burning sensation upon sun exposure. A highly beneficial treatment is afamelanotide, an analogue of alpha-melanocyte–stimulating hormone, which is administered as a subcutaneous implant (16 mg) every 2 months.[8] The skin damage in porphyria cutanea tarda and erythropoietic protoporphyria is from the visible light range; therefore, topical sunscreens are not effective because they are designed to protect against only UV radiation. However, tinted sunscreens containing iron oxides and pigmentary titanium dioxide protect against visible light.

PAPULOSQUAMOUS (INCLUDING FUNGAL) DISEASES

Common papulosquamous diseases are listed in Table 405-4.

PSORIASIS

EPIDEMIOLOGY

Psoriasis occurs in about 3% of the general population,[9] with considerable variation in different parts of the world. It affects male and female patients equally. Approximately one third of the patients have a positive family history. Psoriasis has a bimodal peak of onset, at 22.5 years of age and again at age 55 years.

PATHOBIOLOGY

Psoriasis involves the innate and adaptive immune systems, with abnormal keratinocyte proliferation. Factors playing a role in the pathogenesis include activation of antigen-presenting cells and development of T_H1 and T_H17 cells. Mediators include IL-17, IL-23, and tumor necrosis factor-α (TNF-α).

Psoriasis has a complex, polygenetic inheritance. Cutaneous psoriasis is strongly associated with human leukocyte antigen–Cw6 (HLA-Cw6). To date, genome-wide studies have identified more than 85 non–major histocompatibility complex loci that may increase the risk for psoriasis.

CLINICAL MANIFESTATIONS

Several distinct forms of psoriasis are recognized.[10] *Psoriasis vulgaris,* the most common type, appears as a persistent erythematous plaques with silvery scales most commonly on elbows, knees, and scalp (Fig. 405-13). *Guttate psoriasis* usually occurs after viral or bacterial (most commonly streptococcal) infection; it appears as small, erythematous, scaly papules scattered over a large area of the body in a raindrop distribution (*guttate* means "droplike"). *Inverse psoriasis* refers to psoriasis that occurs in skinfold areas such as the groin, axilla, and inframammary folds. It appears as an erythematous, somewhat shiny patch; because of the constant friction in the involved areas, scales are absent. *Nail psoriasis* includes nail pittings, yellowish macules underneath the nail plate ("oil drop" sign), and thickening of the nail (onychodystrophy) (Fig. 405-14). *Erythrodermic psoriasis* appears as widespread erythroderma with fine silvery scales. *Palmoplantar psoriasis* manifests as keratotic scaly patches and plaques on the palms and soles, very frequently with accompanying fissures. *Pustular*

FIGURE 405-14. Psoriasis. Thickening and crumbling of the nail plate (onychodystrophy). Note the erythematous patches with silvery scales in the periungual area.

psoriasis of von Zumbusch is a rare variant of psoriasis occurring with generalized pustules that are 2 to 3 mm in diameter (Fig. 405-15) and associated with the onset of fever.[11]

Of patients with psoriasis, 5 to 30% also may have psoriatic arthritis, which in about 20% of patients may precede the appearance of cutaneous lesions (Chapter 244). Psoriasis also is associated with chronic kidney disease, inflammatory bowel disease, hepatic disease, certain malignancies, infections, mood disorders, diabetes, major cardiovascular events, and mortality that warrant cholesterol reduction therapy analogous to what would be prescribed in high-risk primary prevention (Chapter 190). The association of psoriasis with HIV infection (Chapter 359) has been well documented.

DIAGNOSIS

The diagnosis usually can be made based on the history and physical examination alone. However, in patients with erythrodermic psoriasis, skin biopsy is needed to exclude other causes of generalized erythroderma, such as drug eruption, cutaneous T-cell lymphoma (Chapter 171), and pityriasis rubra pilaris.

TREATMENT

Treatment, which should be based on extent and areas involved with psoriasis, include topical therapy, phototherapy, oral agents, and injectable biologics (Table 405-5).[12] In general, biologics are more effective than oral treatments,[13] and newer biologics (e.g., ixekizumab, brodalumab, guselkumab, risankizumab, and bimekizumab) appear to be more effective than ustekinumab, etanercept, secukinumab, and adalimumab.[A9–A14] Roflumilast (a phosphodiesterase-4 inhibitor) cream and tapinarof cream (a topical aryl hydrocarbon receptor–modulator) are new FDA-approved topical agents.[A15]

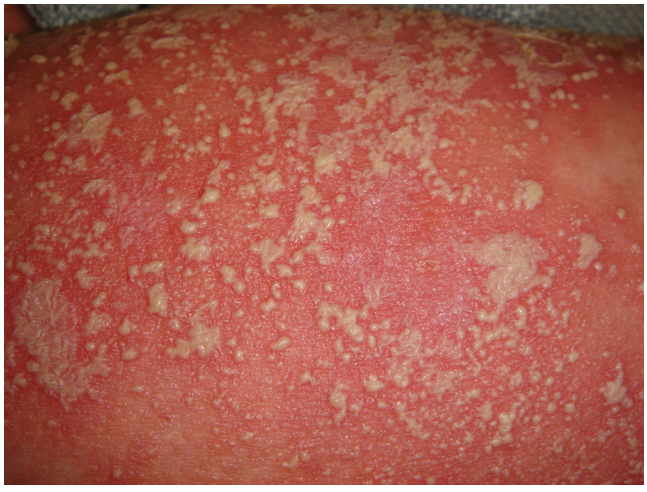

FIGURE 405-15. Pustular psoriasis. Erythematous patch with pustules in a patient with active disease.

TABLE 405-5 SEQUENTIAL THERAPEUTIC APPROACH IN PSORIASIS

Topical agents	Corticosteroids (e.g., triamcinolone ointment 0.1%) Vitamin D analogues (e.g., calcipotriene cream 0.005%) Retinoids (e.g., tazarotene cream 0.1%) Aryl hydrocarbon receptor agonist (tapinarof cream) Phosphodiesterase-4 inhibitor (roflumilast)
Phototherapy	Narrowband ultraviolet B (three times/wk)
Traditional systemic therapy	Methotrexate (10-20 mg/wk) Cyclosporine (3-5 mg/kg/day) Acitretin (25-50 mg/day)
Oral phosphodiesterase-4 inhibitor	Apremilast (30 mg twice/day)
Oral tyrosine kinase-2 inhibitor	Deucravacitinib (6 mg/day)
Biologics	TNF-α inhibitors • Etanercept (50 mg/wk SQ) • Adalimumab (40 mg every 2 wk SQ) • Certolizumab (400 mg SQ every 2 wk SQ) • Infliximab (5-10 mg/kg every 8 wk IV) IL-12/23 inhibitor • Ustekinumab (45-90 mg every 12 wk SQ) IL-17 inhibitors • Secukinumab (300 mg/wk for 5 weeks, followed by 300 mg every 4 wk SQ) • Ixekizumab (160 mg at wk 0, followed by 80 mg every 2 wk from week 2 to 12, then 80 mg every 4 wk SQ) IL-17 receptor antibody • Brodalumab (210 mg at wk 0, 1, 2, then every 2 wk SQ) IL-23 inhibitors • Guselkumab (100 mg wk 0, 4, then every 8 wk SQ) • Tildrakizumab (100 mg at wk 0, 4, then every 12 wk SQ) • Risankizumab (150 mg wk 0, 4, then every 12 wk SQ) IL-36 inhibitor • Spesolimab-sbzo (for flare of pustular psoriasis; 900 mg IV, may repeat 1 wk later)
Potential future treatments*	IL-17 inhibitor • Bimekizumab (320 mg every 4 weeks SQ)

*Doses may change if and when approved by the U.S. Food and Drug Administration.
IL = interleukin; IV = intravenously; SQ = subcutaneously; TNF = tumor necrosis factor; wk = week.

Biologics may increase the risk of infection, so patients should be screened for tuberculosis, HIV, and hepatitis before beginning therapy and not be started on them if such testing is positive unless these conditions are treated. Oral corticosteroids should not be used because psoriasis may worsen when they are discontinued. For the treatment of psoriatic arthritis, please see Chapter 244.

PITYRIASIS RUBRA PILARIS

EPIDEMIOLOGY

Pityriasis rubra pilaris occurs equally in men and women; the incidence ranges from 1 in 5000 new dermatology patients in Great Britain to 1 in 50,000 in India. This disease most frequently occurs as the acquired form, although a familial form (autosomal dominant with variable expression) occasionally has been reported. The pathophysiology is autoinflammatory in nature.

CLINICAL MANIFESTATIONS

The most common form of pityriasis rubra pilaris is type I, which is characterized by widespread salmon-colored plaques with fine scales, islands of sparing, scaliness on the scalp, waxy keratoderma of the palms and soles, and follicular hyperkeratosis (Figs. 405-16 and 405-17). In adult patients, the condition typically starts on the face and moves to the lower extremities; in the juvenile form, it usually starts in the lower half of the body. Ectropion and pruritus may occur.

DIAGNOSIS

Diagnosis is based on the clinical presentations and by the characteristic histologic findings of alternating vertical and horizontal parakeratosis in the stratum corneum.

TREATMENT

The most effective treatment is with oral retinoids (acitretin, 25 to 50 mg/day for 2 to 4 months). Some patients benefit from methotrexate (7.5 to 15 mg/week) or cyclosporine (3 to 5 mg/kg/day). Biologics targeting TNF, IL-12/23, IL-17, and IL-23, used at the same doses as for psoriasis, may be helpful for patients with recalcitrant type I disease. Topical keratolytic agents, such as ammonium lactate lotion 12%, twice daily, are helpful as adjunctive therapy.

PITYRIASIS ROSEA

EPIDEMIOLOGY AND PATHOBIOLOGY

The incidence of pityriasis rosea has been reported as 3 to 30 per 1000 patients. It occurs in all ethnic groups, most commonly in the third and fourth decades of life, with a slight female predominance. A possible association with human herpesvirus types 6 and 7 has been reported.

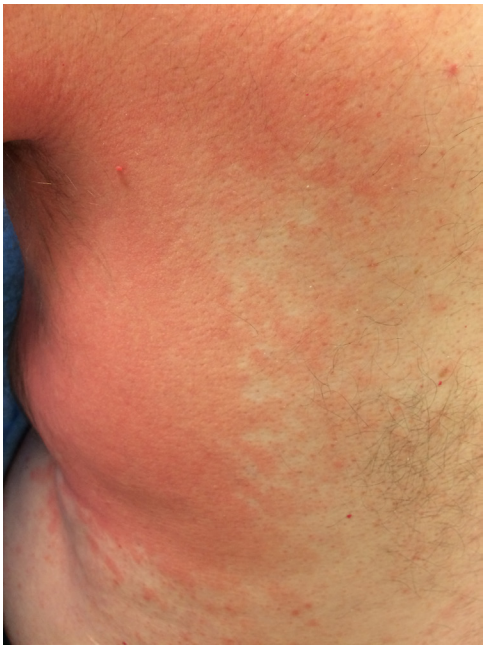

FIGURE 405-16. Pityriasis rubra pilaris. Note the erythematous orange patch with islands of sparing at the edge of the erythematous lesion.

CLINICAL MANIFESTATIONS

In 50 to 90% of patients, pityriasis rosea starts with a primary lesion (herald patch), which is an erythematous, scaly, oval patch a few centimeters in diameter (Fig. 405-18). This lesion is usually followed within a few days by smaller, minimally pruritic, erythematous scaly patches on the trunk, less commonly on the proximal extremities. As a rule, the palms and soles are spared. The distribution of the eruption, especially on the back, tends to follow the lines of cleavage of the skin, with a resulting "Christmas tree" distribution. The eruption is self-limited and resolves within 6 to 8 weeks. In rare instances, lesions may persist.

DIAGNOSIS

The diagnosis usually can be made clinically.[14] The most important differential diagnosis is secondary syphilis, which, in contrast to pityriasis rosea, usually involves the palms and soles. Serology testing to exclude syphilis (Chapter 295) is advisable.

TREATMENT

Treatment is primarily symptomatic, including topical corticosteroids and oral antihistamines.

LICHEN PLANUS

EPIDEMIOLOGY

Lichen planus occurs most commonly in patients between 30 and 60 years of age. Women are affected more frequently than men. The prevalence is less than 1%.

FIGURE 405-17. Pityriasis rubra pilaris. Palmar hyperkeratosis with waxy scales.

FIGURE 405-18. Pityriasis rosea. Large erythematous oval patch (herald patch) accompanied by smaller erythematous patches.

PATHOBIOLOGY

Histologically, lichen planus is characterized by dense T-cell infiltrate at the dermal-epidermal junction, suggesting the pathogenic role of cell-mediated immunity. Because lichen planus or lichen planus–like eruptions can occur after exposure to drugs or chemicals (e.g., color film developer), the role of drugs and chemicals in inducing a T-cell–mediated response against the epidermis has been postulated. Lichen planus may be associated with hepatitis C infection (Chapter 135).

CLINICAL MANIFESTATIONS

Patients present with pruritic erythematous-to-violaceous flat-topped papules, often with white lacy lines (Wickham striae) and most commonly on the wrists, hands, forearms, and genitalia (Fig. 405-19). *Oral lichen planus* occurs as white reticulated lines, most commonly along the bite line on the buccal mucosa. Similar lesions can be seen on the tongue (Fig. 405-20) and genital mucosa. Painful erosion may occur. *Hypertrophic lichen planus* usually occurs on the lower extremities as pruritic lichenified, violaceous plaques.

DIAGNOSIS

The diagnosis is made clinically and is confirmed by the characteristic histologic findings.

FIGURE 405-19. Lichen planus. Violaceous macules and papules on the lateral aspect of dorsum of a hand.

FIGURE 405-20. Lichen planus of the tongue. Note white plaques on dorsal surface of the tongue, with reticulated white line on the distal aspect of the tongue.

TREATMENT

Therapeutic options depend on the location of lesions (Table 405-6). Without treatment, cutaneous lesions usually resolve in approximately 1 year, whereas oral and hypertrophic lesions tend to be much more chronic, persisting for an average of 4.5 years and 8.5 years, respectively.

LICHEN NITIDUS

Lichen nitidus is a rather uncommon condition that usually occurs in dark-skinned children or young adults. The incidence has been estimated to be 3.4 cases per 10,000 persons. The cause is unclear.

The lesions are asymptomatic, 1- to 2-mm, shiny, skin-colored discrete papules, sometimes with fine scales on their surface, occurring most commonly on the genitalia or forearms and occasionally on the trunk (Fig. 405-21). Histologically, a dense, focal lymphocytic infiltrate is seen in the superficial dermis and at the dermal-epidermal junction.

The diagnosis can be confirmed from the typical clinical appearance and the characteristic histologic changes. The condition tends to remit spontaneously in a few years. Therapy with topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 2 weeks) and oral antihistamines (e.g., fexofenadine, 180 mg every morning, and hydroxyzine, 25 to 50 mg at bedtime, as needed) should be reserved for symptomatic cases only.

TABLE 405-6 THERAPEUTIC OPTIONS FOR LICHEN PLANUS

CUTANEOUS LESIONS
Topical corticosteroids (triamcinolone ointment 0.1% twice/day)
HYPERTROPHIC LESIONS
Intralesional corticosteroids (triamcinolone suspension 3-5 mg/mL)
ORAL LESIONS
Corticosteroid paste (triamcinolone 0.1% paste twice/day) or cyclosporine solution (100 mg/mL, 2 mL, twice/day, swish and spit)
GENERALIZED LICHEN PLANUS, PAINFUL ORAL/GENITAL EROSIONS, RECALCITRANT DISEASE
Narrowband UVB phototherapy (two to three times/wk) Hydroxychloroquine 5 mg/kg daily Oral prednisone (0.5-1 mg/kg/day, taper in 6-8 wk) Mycophenolate mofetil (1-2 g/day) Cyclosporine (3-5 mg/kg/day) Tumor necrosis factor-α inhibitors (see Table 405-5)

UV = ultraviolet.

FIGURE 405-21. Lichen nitidus. Note skin-colored fine papules on the upper back.

SECONDARY SYPHILIS

Lesions typically occur 1 to 2 months after the development of a primary chancre lesion (Chapter 295). However, up to 25% of patients may not remember having a chancre. Once the eruption occurs, it lasts for 1 to 3 months.

Clinically, secondary syphilis results from widespread dissemination of *T. pallidum*, often accompanied by fever, fatigue, and lymphadenopathy. The rash may appear as erythematous macules (roseola syphilitica), erythematous-to-hyperpigmented oval or circular papules and plaques covered with scales, or a maculopapular eruption (Fig. 405-22). Nodular eruption also may occur occasionally. The lesions tend to be widespread, and the palms and soles are very frequently involved (Fig. 405-23). The diagnosis is made based on the history, physical examination, and a positive serology. Skin biopsy shows the proliferation of endothelial cells in the dermis and a dense dermal infiltrate containing many plasma cells. Intramuscular benzathine penicillin G (2.4 million U intramuscularly in a single dose) is currently the recommended treatment.

PITYRIASIS LICHENOIDES

Pityriasis lichenoides occurs as erythematous papules that may be minimally pruritic and covered with scales, scattered on all parts of the body. In the acute form (pityriasis lichenoides et varioliformis acuta [PLEVA]), the central part of the lesions develops vesicles, pustules, and hemorrhages, with eventual crusting of the lesions. The chronic form (pityriasis lichenoides chronica [PLC]) occurs as asymptomatic erythematous-to-hyperpigmented papules and plaques covered with fine scales; the trunk and extremities are common sites. Histologically, both PLEVA and PLC are characterized by dense lymphocytic infiltrates in the dermis, with CD8 lymphocytes predominating in PLEVA and CD4 lymphocytes in PLC.

PLEVA usually resolves in a few months, although it can persist. PLC usually lasts for a few years. Both disorders affect patients of all ages, with a slight male predominance.

Treatment generally follows a sequential order: (1) topical corticosteroids (e.g., triamcinolone ointment, 0.1% twice daily for 1 to 2 weeks) and antihistamines, (2) doxycycline (100 mg twice daily), (3) NB-UVB phototherapy (three times weekly for 8 to 10 weeks with increasing doses of NB-UVB),[15] and (4) methotrexate (7.5 to 15 mg/week).

FIGURE 405-22. Secondary syphilis. Papules with crust on elbow.

FIGURE 405-23. Secondary syphilis. Scaly papules and plaques on the palm.

PARAPSORIASIS

The two common variants of parapsoriasis are large plaque parapsoriasis and small plaque parapsoriasis. The peak incidence is in the fifth decade, although rare cases may begin in childhood. Large plaque parapsoriasis appears as minimally pruritic, oval-to-circular, erythematous-to-hyperpigmented macules and patches with fine scales and superficial atrophy (crinkling atrophy) scattered on all parts of the body (Fig. 405-24). These lesions are usually larger than 5 cm. Large plaque parapsoriasis is considered by some to be a variant of mycosis fungoides (see later). Small plaque parapsoriasis appears as circular-to-oval, erythematous-to-hyperpigmented patches or minimally elevated plaques, with lesions smaller than 5 cm in diameter and usually covered with fine scales. A distinct variant is digitate dermatosis, in which lesions appear along the lines of cleavage, usually on the lateral aspect of the trunk in the shape of fingerprints. Histologically, large plaque parapsoriasis is characterized by a dermal lymphocytic infiltrate, which may extend into the epidermis, whereas small plaque parapsoriasis is characterized by spongiotic dermatitis, with a mild superficial lymphocytic infiltrate in the dermis. In up to one third of patients, large plaque parapsoriasis may evolve into mycosis fungoides. As a result, treatment of large plaque parapsoriasis is similar to that of early-stage mycosis fungoides: high-potency topical corticosteroids, NB-UVB phototherapy, and psoralen and UVA (PUVA). By comparison, patients with small plaque parapsoriasis have a benign course, and management should be symptomatic only, with emollients, topical corticosteroids, and if needed, NB-UVB phototherapy.

MYCOSIS FUNGOIDES

Mycosis fungoides is the most common variant of cutaneous T-cell lymphoma (Chapter 171). The four types of cutaneous manifestations are patch, plaque, tumor, and erythrodermic.[16] Patch-stage disease manifests as asymptomatic or pruritic skin-colored or minimally erythematous patches with fine "cigarette paper" wrinkling of the epidermis (Fig. 405-25); hyperpigmented or hypopigmented lesions are frequently seen in dark-skinned patients. The patches can vary from a few millimeters to a few centimeters in diameter; they are more common on sun-protected areas such as the buttocks. Lesions may be present for years. As the disease progresses, some of the patches may become more indurated and may evolve into plaques (Fig. 405-26). Nodular lesions may occur in patients without any patch or plaque lesions, although

FIGURE 405-24. Large plaque parapsoriasis. Erythematous patches with fine scales.

FIGURE 405-25. Mycosis fungoides. Erythematous minimally elevated plaque with "cigarette paper" wrinkling of the epidermis.

FIGURE 405-26. Mycosis fungoides. Erythematous plaques with annular elevated borders.

more commonly these lesions occur in conjunction with patches and plaques. Erythrodermic mycosis fungoides occurs as a generalized erythroderma with significant scaling and pruritus. Hyperkeratosis of the palms and soles and fissuring of hands and feet are quite common.

The diagnosis is confirmed by histologic demonstration of atypical mononuclear cells both in the epidermis and in the dermis, as well as immunophenotypic markers showing predominance of CD4 cells in the infiltrate. Treatment options are summarized in Table 405-7.[17]

BAZEX SYNDROME AND NECROLYTIC ACRAL ERYTHEMA

Patients with Bazex syndrome (acrokeratosis neoplastica) present with symmetrical, scaly, erythematous-to-violaceous hyperkeratotic plaques on acral areas, such as digits, palms, soles, nose, and ears. Almost all have involvement of the ears and ridging of the nails. Bazex syndrome is associated with malignancy, especially of lips, tongue, larynx, pharynx, and esophagus, perhaps because of cross-reactivity between tumor antigens and normal keratinocytic antigens.

TABLE 405-7 TREATMENT FOR MYCOSIS FUNGOIDES

CLINICAL TYPE	TREATMENT
Patch and localized plaque	Topical corticosteroids (e.g., triamcinolone ointment 0.1% q12h) Topical retinoids (e.g., bexarotene gel 1%, one to four times/day) Imiquimod cream three times/wk Topical mechlorethamine gel 0.016% daily Narrowband UVB (two to three times/wk)
Extensive plaques and tumors	Psoralen and UVA (PUVA; two to three times/wk) Oral bexarotene (300 mg/m^2/day) Methotrexate (15-25 mg/wk SQ) Pegylated interferon-α2A (180 μg SQ weekly) Total skin electron beam therapy Histone deacetylase inhibitors: vorinostat (400 mg/day PO); romidepsin (14 mg/m^2 IV on days 1, 8, and 15 of a 28-day cycle) Low-dose pralatrexate (15 mg/m^2 IV, weekly for 6 wk in a 7-wk cycle) Brentuximab vedotin (1.2-1.8 mg/kg, maximum dose: 150 mg IV every 3 wk) Mogamulizumab (1 mg/kg IV on days 1, 8, 15, 22 [cycle 1]; then days 1 and 15 on subsequent cycles, every 28 days) Alemtuzumab (30 mg IV three times weekly for 10-12 wk) Gemcitabine (750-1000 mg/m^2, IV, weekly for 3 wk cycles) Pegylated liposomal doxorubicin (20 mg/m^2, IV, every 2-4 wk) Radiation therapy for localized tumors
Erythrodermic	Extracorporeal photopheresis (2 consecutive days every 2-4 wk)

IV = intravenously; PO = orally; SQ = subcutaneously; UVA = ultraviolet A; UVB = ultraviolet B; wk = week.

FIGURE 405-27. Necrolytic acral erythema. Lichenified plaques with fine scales on anterior lateral ankle.

Necrolytic acral erythema is a marker of chronic hepatitis C infection (Chapter 135). It manifests with well-defined hyperkeratotic, lichenified plaques on the dorsum of the hands and feet (Fig. 405-27). Low serum zinc levels have been reported in some patients whose disease improved after oral zinc therapy.

DERMATOPHYTOSES

Fungal infections that occur as papulosquamous eruptions include tinea corporis, tinea manuum, tinea cruris, and tinea pedis. *Tinea corporis* manifests as a polycyclic erythematous scaly patch that has elevated borders consisting of papules and pustules; the border advances centrifugally. The trunk is the most common site. *Tinea cruris* has similar morphology, except it is located in the inguinal folds (Fig. 405-28). *Tinea manuum* presents as an erythematous

FIGURE 405-28. Tinea cruris. Erythematous patch with erythematous papules and scales at the periphery.

FIGURE 405-29. Tinea versicolor. Hypopigmented patches on the trunk.

scaly patch with an advancing active border, usually located on the dorsum of the hands, or it may occur as diffuse scaly patches with mild hyperkeratosis involving part or the entire surface of the palm and palmar aspect of the fingers. *Tinea pedis* can occur as scaly macerated lesions with erythema in the toe webs, or as patchy or diffuse scaliness on the sole extending to the medial and lateral aspect of the foot (moccasin distribution). The latter presentation can be associated with diffuse scaliness of one but not both palms, a condition known as the "one-hand, two-feet syndrome." The diagnosis can be confirmed by examination of skin scrapings using 10% potassium hydroxide preparation or by fungal culture. Treatment consists of topical or oral antifungal medications (e.g., clotrimazole cream, 1%, twice daily for 2 to 4 weeks, or terbinafine, 250 mg for 2 to 12 weeks), depending on the site involved. Nail involvement (Chapter 409) is best treated with systemic therapy, although typical therapies can be useful as well.

TINEA VERSICOLOR

Tinea versicolor is a fungal infection of the skin caused by *Malassezia globosa*. It occurs in otherwise healthy young individuals, especially in warm and moist environments during the summer. The prevalence is estimated to be 2 to 8% in the United States and up to 50% in the tropical countries. Clinically, it appears as asymptomatic macules and patches with very fine scales; the color can be hypopigmented, skin colored, minimally erythematous, or light brown (Fig. 405-29). The patches start as perifollicular macules, with the midchest and midback the most common sites. The diagnosis is confirmed by the characteristic appearance of the fungal elements on a 10% potassium hydroxide preparation—grapelike clusters of yeast and short, septate branching hyphae ("spaghetti and meatballs" appearance). Treatment is with zinc pyrithione 1% shampoo (applied for 5 minutes then washed off, daily for 2 weeks), topical antifungal preparations (e.g., clotrimazole cream, 1% twice daily for 4 weeks), or fluconazole 300 mg once weekly for 2 weeks.

FIGURATE ERYTHEMAS

The figurate erythemas (which include erythema annulare centrifugum, erythema gyratum repens, and erythema chronicum migrans) appear as erythematous circular or polycyclic plaques with central clearing and, frequently, a centrifugally migrating border. Occasionally, fine scaling also may be observed. The extremities are the most common sites. The diagnosis frequently can be made by the typical history and morphologic features.

Erythema annulare centrifugum is most commonly idiopathic; however, it also can be a manifestation of a hypersensitivity response to medications. Management includes identification of a precipitating agent (if possible) and treatment with topical or systemic corticosteroids. *Erythema gyratum repens* occurs as concentric erythematous plaques with fine scales, resembling a wood-grain pattern. This unusual form of figurate erythema has been associated with malignant hematologic diseases and with carcinomas of the breast, lung, gastrointestinal tract, prostate, and cervix. Treatment of the underlying malignant disease results in the resolution of the skin lesion in a few months. *Erythema chronicum migrans* is a cutaneous manifestation of Lyme disease and is caused by the spirochete *Borrelia burgdorferi* (Chapter 296); it appears as a concentric ring of erythema that progresses centrifugally from the site of a tick bite. Occasionally, it may appear as a circular erythematous patch. The diagnosis is made by a history of a tick bite, the characteristic cutaneous lesion, or elevated serum antibodies to *B. burgdorferi*. Management is the same as for Lyme disease.

406 MACULAR, PAPULAR, PURPURIC, VESICULOBULLOUS, AND PUSTULAR DISEASES

DANIELA KROSHINSKY

MACULAR AND PAPULAR EXANTHEMS

An exanthem, which is an acute generalized eruption of the skin, can be scarlatiniform or morbilliform. Scarlatiniform eruptions consist of innumerable small papules that coalesce into confluent blanching erythema (Chapter 338). Morbilliform eruptions are erythematous macules and flat papules that resemble the eruption of measles. Morbilliform eruptions can be caused by viral infections or by hypersensitivity reactions to medications (Chapter 407) (Table 406-1).

TABLE 406-1 EXANTHEMS

SCARLATINIFORM ERUPTIONS
Scarlet fever (see below)
Toxic shock syndrome (Chapter 269)
Kawasaki disease (Chapter 249)
MORBILLIFORM ERUPTIONS
Measles (Chapter 338)
Rubella (Chapter 339)
Erythema infectiosum (Chapter 342)
Roseola (Chapter 345)

SCARLATINIFORM ERUPTIONS

SCARLET FEVER

Scarlet fever is a sequela of toxin-producing β-hemolytic streptococcal infection (Chapter 269) of the ears, nose, throat, or skin, although *Staphylococcus aureus* (Chapter 267), *Haemophilus influenzae* (Chapter 277), or *Clostridioides* spp. (Chapter 271) cause occasional cases. The skin lesions often are accompanied by fever, headache, malaise, chills, sore throat, and vomiting.

On physical examination, the mucous membranes are usually erythematous with petechiae. A white membrane is often seen on the tongue, and tonsillitis may be present. The rash, which appears after the fever, is typically fine erythematous papules, beginning on the upper torso and then spreading. The face is characteristically flushed, with circumoral pallor. The rash persists for 4 to 5 days and is followed by desquamation.

Treatment is oral penicillin V 500 mg two to three times daily for 10 days or a single dose of intramuscular benzathine penicillin G (1.2 million units). Clinical recovery may take only 4 to 5 days but the rash typically takes several weeks to resolve.

TOXIC SHOCK SYNDROME

Toxic shock syndrome is an acute febrile illness, usually caused by toxin-producing *S. aureus* (Chapter 267) but sometimes caused by *Streptococcus* spp. (toxic shock–like syndrome [Chapter 269]). Most cases are in previously healthy adults between 20 and 50 years of age.

CLINICAL MANIFESTATIONS

The clinical manifestations of toxic shock syndrome are a result of the massive release of tumor necrosis factor-α (TNF-α) and interleukin-1: fever, diffuse macular erythema (Fig. 403-5 in Chapter 403), severe conjunctival involvement, and erythema of the mucous membranes of the lungs, liver, gastrointestinal tract, and kidneys. Blood cultures are positive in about 5 to 15% of patients who have staphylococcal toxic shock syndrome and about 50% of patients who have streptococcal toxic shock–like syndrome.

TREATMENT

For staphylococcal toxic shock syndrome caused by methicillin-sensitive organisms, treatment is oxacillin or nafcillin (2 g IV every 4 hours) or cefazolin (2 g IV every 8 hours) in the setting of a true penicillin allergy plus clindamycin (900 mg IV every 8 hours). For staphylococcal toxic shock syndrome due to methicillin-resistant *S. aureus*, treatment is vancomycin (15 to 20 mg/kg every 8 to 12 hours, not to exceed 2 g per dose) plus clindamycin (900 mg IV every 8 hours).

Streptococcal toxic shock syndrome should be empirically treated with clindamycin (900 mg IV every 8 hours) plus penicillin G (4 million units IV every 4 hours) until susceptibilities return. Alternatives to penicillin are ceftriaxone (1 to 2 g IV every 12 hours), cefazolin (1 to 2 g IV every 8 hours), vancomycin (30 mg/kg/day IV in two divided doses) or daptomycin (6 mg/kg IV every 24 hours).

PROGNOSIS

Desquamation of the skin of the palms and soles typically occurs 1 to 2 weeks after the onset. Staphylococcal toxic shock syndrome has a mortality of 5 to 15%, whereas the mortality rate for streptococcal toxic shock–like syndrome can be five times higher.

KAWASAKI DISEASE

Kawasaki disease (Chapter 249), which is a systemic vasculitis of unknown etiology, is primarily an illness of children under age 5 years, but it also can occur in adults. It is far more common in patients of Northwestern Asian descent.[1]

CLINICAL MANIFESTATIONS

Patients typically present with very high fever and a scarlatiniform, morbilliform, urticarial, or targetoid rash. Other features include conjunctival infection, hemorrhagic and dry, fissured lips, a "strawberry tongue," and cervical lymphadenitis. Arthralgias, frank arthritis, urethritis, diarrhea, pneumonitis, and aseptic meningitis can occur, but the most serious complications in untreated patients are coronary artery aneurysms and myocarditis.

DIAGNOSIS

No diagnostic tests are helpful, so the diagnosis is clinical and is based on the typical rash and the development of myocarditis.

TREATMENT

Acute treatment is a single infusion of 2 g/kg of IV gamma globulin (IVIG) given over 8 to 12 hours within 10 days of the onset of fever. Aspirin (30 to 50 mg/kg/day divided into 4 daily doses until defervescence, then reduced to 3 to 5 mg/kg/day) is also indicated. The concomitant use of supplemental intravenous corticosteroids under expert supervision results in a lower incidence of coronary artery aneurysm in at-risk individuals.[2]

MORBILLIFORM ERUPTIONS

Acute viral infections that can cause morbilliform rashes include measles (Chapter 338), rubella (Chapter 339), erythema infectiosum (Chapter 342), and roseola (Chapter 345). With measles, the enanthem (Koplik spots; see Fig. 338-2 in Chapter 338) precedes the exanthem (Fig. 338-3 in Chapter 338) by 1 to 2 days and persists for 2 to 4 days. The exanthem begins on the fourth or fifth day, typically with papules on the face and behind the ears, with subsequent spread to the trunk and extremities. The exanthem of rubella (Fig. 339-1 in Chapter 339) starts as pink facial macules and papules that spread to the trunk and extremities and that persist for only 1 to 3 days. In erythema infectiosum (Chapter 342), a bright red erythema develops suddenly over the cheeks (Fig. 342-1 in Chapter 342), followed within 1 to 4 days by an erythematous morbilliform rash on the extremities (Fig. 406-1). In roseola (Chapter 345), 2 or so days of pink papules or blanchable macular erythema typically follow defervescence after a high fever.

These viruses are typically diagnosed on clinical grounds, but polymerase chain reaction testing is both sensitive and specific.[3] For each of these viruses, treatment is supportive because no antiviral therapy is efficacious.

PAPULAR ERUPTIONS

INFECTIOUS ERUPTIONS

Molluscum Contagiosum

In molluscum contagiosum (Chapter 343), patients develop individual, grouped, or widely disseminated, skin-colored or pink papules that are firm, smooth, frequently umbilicated, and usually 2 to 6 mm in diameter (Fig. 406-2). In patients who are infected with human immunodeficiency virus (HIV), hundreds of lesions may be seen. The diagnosis is clinical.

ABSTRACT

Macular, papular, purpuric, vesiculobullous, and pustular diseases include exanthems, toxin-mediated diseases, primary skin infections, vasculitis, embolic phenomena, thrombotic sequelae, autoimmune blistering diseases, and hypersensitivity reactions. By using a systematic morphologic approach, the general physician can generate a differential diagnosis for each type of skin lesion, understand the underlying pathogenesis, and decide on appropriate medical therapy or referral options.

Treatment options include cryotherapy with liquid nitrogen, curettage, cantharidin, podophyllin, and oral cimetidine (up to 40 mg/kg/day).

Warts

Warts are benign skin and mucosal proliferations caused by over 150 types of human papillomaviruses (HPVs) (Chapter 344). Common warts, which can occur anywhere on the body, are firm, hyperkeratotic papules ranging in size from 1 mm to more than 1 cm (Fig. 406-3). Other variants include genital warts, flat warts, and deep palmoplantar warts. The diagnosis is clinical, but biopsy should be performed on larger or atypical lesions to exclude malignant transformation. Common topical treatments include liquid nitrogen, cantharidin, or podophyllin, as well as prescription-strength salicylic acid, imiquimod, 5-fluorouracil, or cidofovir. Over-the-counter liquid nitrogen is not as cold and, as a result, not as effective as in-office treatment. Repeat cryotherapy is usually required until clearance is achieved.

PURPURIC ERUPTIONS

Purpuric eruptions occur when the extravasation of blood results in visible skin or mucosal hemorrhage. They are classified based on: their size as petechiae (≤4 mm; Table 406-2; Fig. 406-4), macular purpura (>4 to 10 mm; Fig. 406-5), or ecchymoses (>10 mm); and their morphology as palpable purpura (Table 406-3), and inflammatory and noninflammatory retiform purpura (Table 406-4).

TABLE 406-2 DIFFERENTIAL DIAGNOSIS OF MACULAR PETECHIAE, PURPURA, AND ECCHYMOSES

MACULAR PETECHIAE (≤4 mm IN DIAMETER)
Thrombocytopenia (platelets <50,000/μL) (Chapter 158)
Increased venous pressure
Trauma (Chapter 97)
Vitamin C deficiency (Chapter 199)
Pigmented purpuric eruptions
Waldenström macroglobulinemia (Chapter 173)
MACULAR PURPURA (5-9 mm)
Waldenström macroglobulinemia (Chapter 173)
Thrombocytopenia with infection or inflammation (Chapter 158)
Cutaneous small vessel vasculitis (Chapter 249)
MACULAR ECCHYMOSES (≥1 cm)
Anticoagulation (Chapter 70)
Hepatic insufficiency (Chapters 148 and 149)
Vitamin K deficiency (Chapter 161)
Disseminated intravascular coagulation (Chapter 161)
Actinic (solar, senile) purpura
Corticosteroid therapy, topical or systemic
Vitamin C deficiency (Chapter 199)
Systemic amyloidosis (Chapter 174)
Ehlers-Danlos syndrome (Chapter 239)
Thrombocytopenia (Chapter 158)
Platelet function defects (e.g., von Willebrand disease; Chapter 159)

NONPALPABLE PURPURA

Petechiae

A common cause of petechiae is Schamberg disease, which is a pigmented purpuric dermatitis in which petechiae result from idiopathic capillaritis. Most often seen in middle-aged to older adults, Schamberg disease presents with yellow-brown patches on the lower legs with overlying petechiae that are cayenne pepper colored. Lesions occasionally can be present on the trunk, buttocks, arms, and thighs. The lesions become hyperpigmented and then fade, with new lesions occurring over time. Topical steroids (see Table 403-10), ascorbic acid 500 mg twice daily, with or without rutoside 50 mg twice daily, can be helpful.

Systemic diseases that can result in petechiae include idiopathic thrombocytopenic purpura (Chapter 158), thrombocytopenia-caused diseases or medications that reduce platelet production (Chapter 158), abnormal platelet function as a result of renal or hepatic insufficiency (Chapters 116 and 139), and clotting factor abnormalities (Chapter 160). Treatment is for the underlying condition.

Macular Purpura

Waldenström macroglobulinemia (Chapter 173) presents with recurrent petechiae and macular purpura on the legs, typically associated with itching,

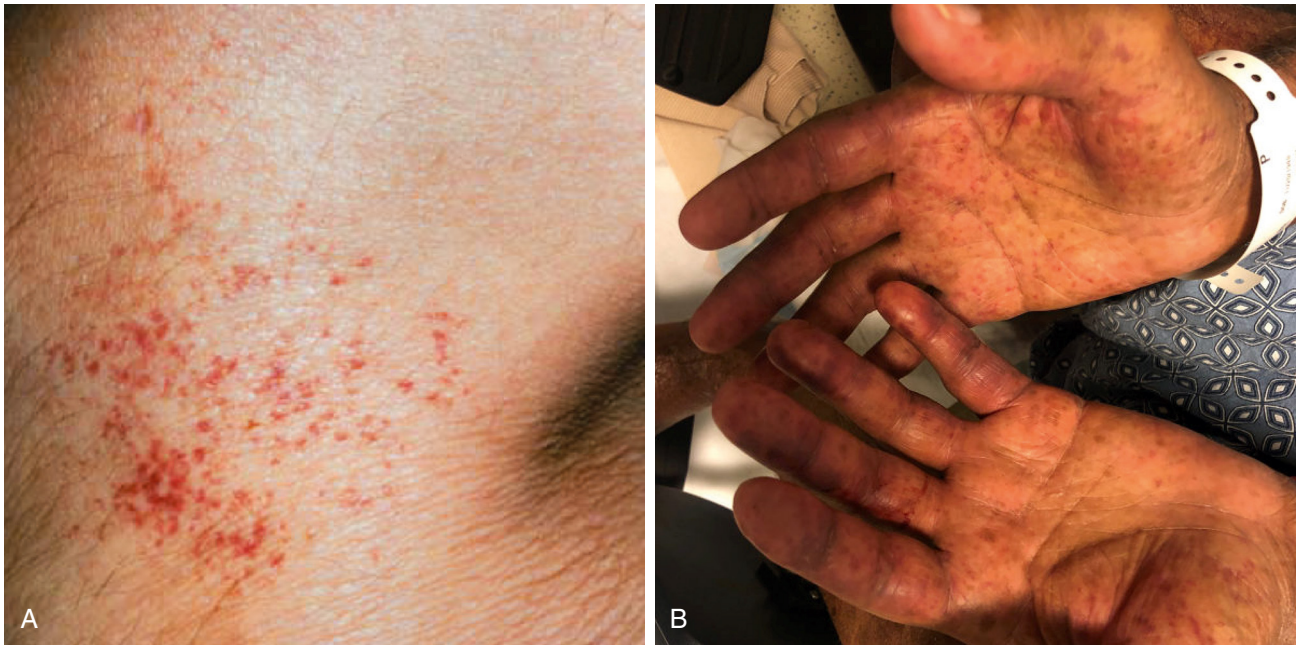

FIGURE 406-4. **Petechiae. A,** Round to oval petechiae, <3 mm in diameter. (From Piette WW. Purpura: mechanisms and differential diagnosis. stinging, or burning in the setting of a polyclonal hypergammaglobulinemia and high immunoglobulin G (IgG) or IgA rheumatoid factor titers. Some patients subsequently develop autoimmune connective tissue disease, especially Sjögren syndrome (Chapter 247) or lymphoma (Chapters 171 and 172).

Ecchymoses

Minor trauma in individuals who have lost dermal connective surrounding blood vessel tissue can result in macular ecchymoses. Solar purpura (Fig. 406-6), which is caused by aging and chronic sun exposure, is commonly seen on the forearms. Steroid purpura, which is related to prolonged treatment with topical or systemic corticosteroids, can develop anywhere on the skin (Chapter 28). Similar systemic examples include systemic amyloidosis (Chapter 174), scurvy (Chapter 199), and Ehlers-Danlos syndrome (Chapter 239).

PALPABLE PURPURA

Vasculitis

Palpable purpura is caused by inflammatory damage to small or small and medium-sized vessels, and the clinical findings depend on the size of the affected vessel.[4] Leukocytoclastic vasculitis, which is the most common form of small-vessel vasculitis (Fig. 406-7), may be idiopathic, but it also can be associated with infection, drug reactions, connective tissue disease, and underlying malignancy.[5] Some cases may be associated with systemic symptoms or systemic lupus erythematosus (Chapter 245).

Pigmented purpuric eruptions (see above)
Waldenström macroglobulinemia (Chapter 173)

DIAGNOSIS

A complete blood count with differential, renal and liver function testing, and urinalysis with microscopy should be performed. Specialized tests should be ordered for idiopathic or chronic cases or based on a thorough review of systems (see Table 406-3) and can include cryoglobulins; rheumatoid factor; serologies for testing for hepatitis B and C, and HIV; levels of total complement, C3, C4; antineutrophil cytoplasmic antibodies (ANCAs); anti-nuclear antibody (ANA); double-stranded DNA (dsDNA); and anti-Ro, anti-La, anti-RNP, and anti-Sm antibodies.

Biopsy and clinical correlation are often required to confirm the clinical diagnosis (E-Fig. 406-1). Skin biopsy specimens taken from lesions within

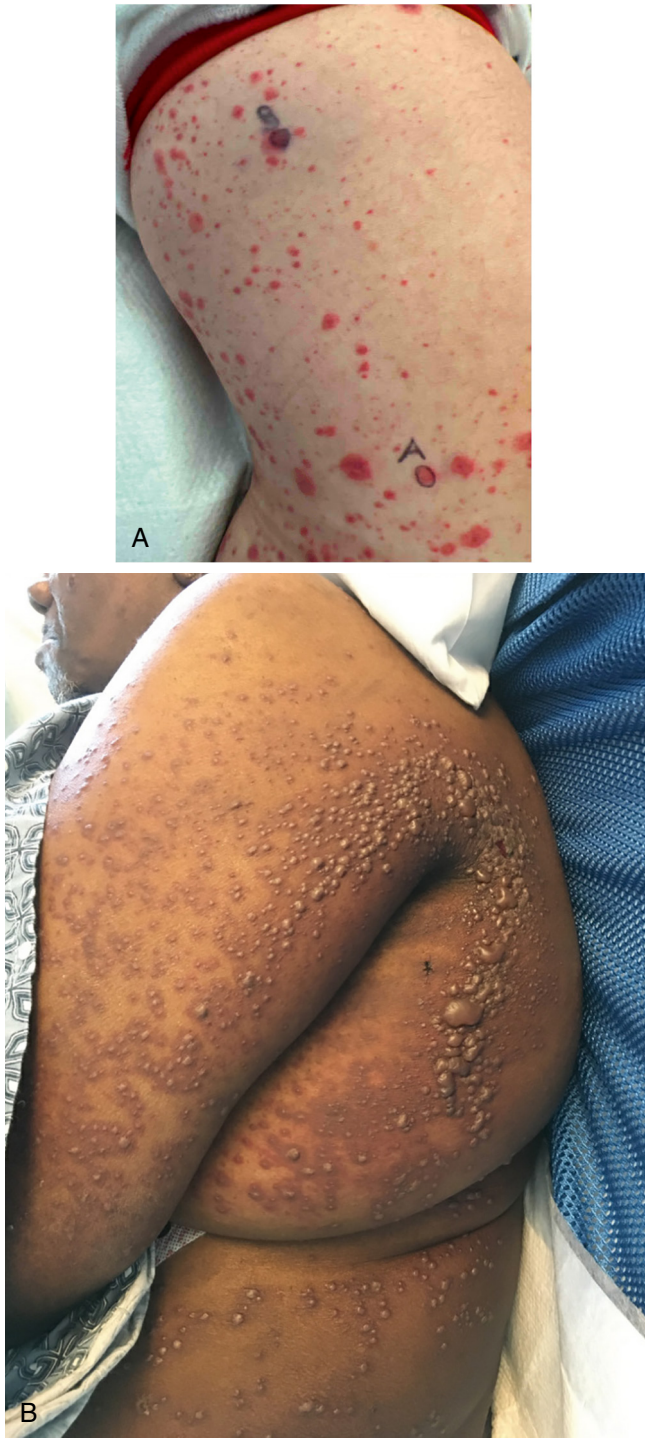

FIGURE 406-7. Palpable purpura. A, Leukocytoclastic vasculitis commonly causes raised purpuric and ulcerated lesions on the legs. **B,** Bullous leukocytoclastic vasculitis. (Courtesy Daniela Kroshinsky, MD MPH.)

48 hours of formation reveal a granular pattern of C3, IgG, IgM, and/or IgA deposits in blood vessel walls on direct immunofluorescence.

Patients with IgA vasculitis/Henoch-Schönlein purpura, which usually follows a streptococcal or staphylococcal infection in adults, have perivascular deposits of IgA and C3 on skin biopsy. Patients may have fever, arthralgias, and abdominal pain, and they are at risk for renal vasculitis (Chapter 107).

Urticarial or hypocomplementemic vasculitis (Chapter 249) generally persists for more than 24 hours and is associated with arthritis, facial and laryngeal edema, and low levels of serum complement. A clinical clue differentiating vasculitis from routine urticaria is that vasculitic lesions may heal with hyperpigmentation or purpura.

TREATMENT

Treatment is based on the diagnosis. For idiopathic leukocytoclastic vasculitis, oral treatment options include colchicine (0.6 mg twice daily); prednisone (1 mg/kg/day); or dapsone (up to 200 mg once daily). In severe cases, immunosuppressive options under expert supervision include mycophenolate mofetil (up to 45 mg/kg); azathioprine (up to 2.5 mg/kg); or cyclophosphamide (up to 2.5 mg/kg) can be continued until the disease becomes inactive.

RETIFORM PURPURA

Retiform purpura is defined as large patches of purpura, each with a netlike or angulated border. Retiform purpura can be inflammatory or noninflammatory but typically is not raised.

FIGURE 406-8. Polyarteritis nodosa. Retiform purpura of the dorsal foot in a patient with *systemic* polyarteritis nodosa. (From Wetter DA, Dutz JP, Shinkai K, et al. Cutaneous vasculitis. In: Bolognia JL, Schaffer JV, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:435.)

Inflammatory Retiform Purpura

Inflammatory retiform purpura is characterized by stellate or branching purpura, but early lesions also demonstrate prominent surrounding erythema (Fig. 406-8) and frequently reflect a vasculitic process. The skin lesions can be associated with microscopic polyangiitis (Chapter 249), granulomatosis with polyangiitis (Chapter 249), and eosinophilic granulomatosis with polyangiitis (Chapter 249).

In granulomatosis with polyangiitis, palpable purpura and oral ulcerations are the most common lesions, but patients may also develop painful subcutaneous nodules and ulcers that mimic pyoderma gangrenosum. In eosinophilic granulomatosis with polyangiitis, the skin disease usually presents as palpable purpura with necrosis on the legs, but retiform purpura, urticaria, subcutaneous nodules, livedo racemosa, and papulonecrotic lesions may be seen.

Skin biopsy and ANCA testing are often key to the diagnosis of these conditions, and treatment is for systemic disease (Chapter 249). The skin lesions generally resolve when the systemic disease responds to treatment.

Noninflammatory Retiform Purpura

Cutaneous Emboli

Cutaneous emboli, especially cholesterol emboli (Chapter 66) and infectious emboli (Chapter 61), can lead to retiform as well as palpable purpura. Cholesterol emboli, which tend to affect older patients with advanced atherosclerotic disease, can occur spontaneously upon fragmentation of an atheromatous plaque or, more commonly, acutely after catheterization, within hours to days after thrombolysis, or months after the initiation of systemic anticoagulation. Other symptoms and signs can include fever, altered mental status, myalgias, weight loss, acute kidney injury (Chapter 106), and new or worsened arterial hypertension. In addition to the acute onset of retiform purpura, patients may also develop cyanosis (Fig. 406-9), distal livedo reticularis, nodules, ulceration, and even gangrene. Up to 80% of patients have peripheral eosinophilia.

Emboli with retiform or palpable purpura can be seen in patients with infectious endocarditis (Chapter 61) and are most commonly seen in acute meningococcemia (Fig. 274-2 in Chapter 274) and disseminated gonococcal infection (Fig. 275-4 in Chapter 275). In ecthyma gangrenosum, patients infected with *Pseudomonas aeruginosa* (Chapter 282) or less commonly *Klebsiella* spp (Chapter 281), *Escherichia coli* (Chapter 280), or *Serratia* spp (Chapter 281) develop erythematous papules and plaques with central purpura and hemorrhagic necrosis. Fungal infections also have been implicated in immunocompromised patients.

Other emboli that may cause petechiae or purpura include fat emboli after bone trauma (Chapters 68 and 97), emboli from an atrial myxoma (Chapter 47) or ventricular thrombus, and emboli from nonbacterial thrombotic endocarditis (Chapter 47).

Thrombi

Noninflammatory retiform purpura can occur when patients with disseminated intravascular coagulation (DIC) (Chapter 161), thrombotic thrombocytopenic purpura (Chapter 158), monoclonal cryoglobulinemia (Chapter 173), calciphylaxis, and drug reactions to warfarin (Chapter 70) develop in situ thrombi. DIC also can be associated with hemorrhagic bullae and purpura fulminans (Fig. 406-10). Cryoglobulinemia (Chapter 173) may be associated with leukemia, lymphoma, multiple myeloma, and Waldenström macroglobulinemia (Chapter 173). Another thrombotic cause of purpura is thrombotic thrombocytopenic purpura (Chapter 158).

FIGURE 406-9. Cholesterol emboli. Both livedo reticularis and retiform purpura are seen distally. (Courtesy Norbert Sepp, MD. From Piette WW. Cutaneous manifestations of microvascular occlusion syndromes. In: Bolognia JL, Schaffer JV, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:399.)

FIGURE 406-10. Purpura fulminans. Purpura and hemorrhagic blisters are seen on the arm of this patient.

Warfarin skin necrosis (Chapter 70), which is an uncommon complication that typically occurs between the third and tenth day of therapy in patients who are not also receiving bridging heparin anticoagulation, presents as painful erythematous to purpuric plaques (especially on the breasts, thighs, and buttocks) that can progress to hemorrhagic bullae. The course of the disease is not dependent on whether or not warfarin therapy is continued.

VESICULOBULLOUS DISEASES

Vesicles are clear, fluid-filled lesions smaller than 1 cm, whereas bullae are similar lesions larger than 1 cm. Causes of vesiculobullous lesions include genetic and immunologic conditions, infections, hypersensitivity reactions, metabolic or physical disorders, and inherited genetic defects (Table 406-5).[6]

IMMUNOLOGICALLY MEDIATED BLISTERING DISEASES

Immunologically mediated blistering diseases are caused by autoantibodies that bind to components of the epidermal desmosome (pemphigoid) or

hemidesmosome (pemphigus), where they activate complement and precipitate inflammation. Inflammatory cell proteases can degrade basement membrane proteins, thereby leading to the formation of subepidermal (pemphigoid) or intraepidermal (pemphigus) blisters.

SUBEPIDERMAL BLISTERING DISORDERS

BULLOUS PEMPHIGOID

Bullous pemphigoid is an autoimmune blistering disease most commonly seen in elderly individuals or as an adverse effect of medications.[7] Patients develop pruritic, tense vesicles, bullae, and urticarial or eczematous plaques on the torso and extremities, including the palms and soles. Mucosal involvement can include the oral, laryngeal, and genital regions (Fig. 406-11). The diagnosis should also be considered in elderly patients who present with chronic, unexplained pruritic eruptions without bullae.

On skin biopsy, the subepidermal blisters have an eosinophilic infiltrate with linear IgG and C3 deposits at the basement membrane and IgG antibodies on the epidermal side. Indirect immunofluorescence, which has a lower sensitivity but higher specificity, can be helpful in assessing with clinically suspicious cases that are not evident on skin histology.[8]

TREATMENT

An ultrapotent (class 1) topical steroid can be used for patients with limited involvement, whereas oral prednisone (1 mg/kg/day) is rapidly effective in patients with moderate and severe disease.[9] Steroid-sparing agents should be initiated under expert supervision to allow steroids to be tapered over several weeks after the formation of new lesions has ceased; effective options include: dapsone (up to 200 mg/day), methotrexate (up to 25 mg weekly), azathioprine (up to 2.5 mg/kg as guided by the patient's thiopurine methyltransferase level), and mycophenolate mofetil (up to 4 g divided into two daily doses). Refractory cases or patients who have side effects from these standard treatments may benefit from IVIG (2 g/kg divided over 2 to 3 days), rituximab (375 mg/m^2 weekly for 4 weeks or 1000 mg given 2 weeks apart), omalizumab[10] (300 mg every 2 to 8 weeks or 375 mg every 2 to 4 weeks), or dupilumab (300 mg every other week) under expert supervision.[11] The duration of therapy is guided by the activity of the disease and its response to medication.

FIGURE 406-12. Pemphigoid gestationis. Multiple tense blisters and erosions on an erythematous base are present. (Courtesy Neil J. Korman, MD.)

PROGNOSIS

In most patients, treatment suppresses the disease until the process fully resolves several years later. Left untreated, bullous pemphigoid generally undergoes spontaneous remissions and exacerbations with a high risk of infection.

PEMPHIGOID GESTATIONIS

Pemphigoid gestationis is a rare autoimmune dermatosis predominantly arising in late pregnancy and/or immediately postpartum, although it can occur at any time during pregnancy. Intensely pruritic periumbilical urticarial plaques, which spread peripherally, progress to vesicles and blisters (Fig. 406-12). The face, palms, soles, and mucous membranes are typically spared. Skin biopsy shows bullous pemphigoid antigen II and linear C3 deposition in the basement membrane.

TREATMENT

Patients with mild disease should be treated with moderate or high-potency topical corticosteroids (see Table 403-10) twice daily to affected areas. Systemic corticosteroids (e.g., prednisone, 0.5 to 1 mg/kg once daily) should be reserved for patients who have extensive disease—usually 1 to 2 weeks of full-dose therapy, followed by a taper to the lowest effective dose. Antihistamines can be helpful in controlling itch. Women should be managed by experienced obstetricians because of the increased risk of premature labor and of the delivery of infants who are small for their gestational age.

MUCOUS MEMBRANE PEMPHIGOID

Mucous membrane pemphigoid presents as blisters on oral, nasopharyngeal, ocular, laryngeal, anogenital, and esophageal surfaces. The scarring associated with their healing can cause substantial morbidity (Fig. 406-13).

Some patients with mucous membrane pemphigoid have circulating IgG autoantibodies against laminin 332 on the dermal side of skin, others have pure ocular disease with IgG antibodies against β_4 integrin, others have mucosal and skin lesions, and yet others have oral but not skin lesions. Biopsy shows

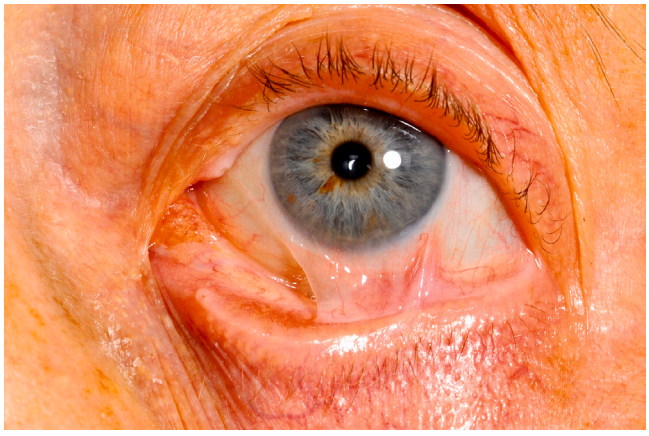

FIGURE 406-13. Mucous membrane (cicatricial) pemphigoid. Typical ocular involvement as manifested by fibrous tracts, representing partial or incomplete symblepharon. (From Bernard P, Borradori L. Pemphigoid group. In: Bolognia J, Schaffer J, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:521.)

subepidermal blister with basement membrane deposits of linear IgG, IgA, and C3, whereas circulating IgG and/or IgA antibodies are seen on indirect immunofluorescence.

TREATMENT

Treatment for mild disease is twice daily potent topical corticosteroids (or intralesional corticosteroids in patients with only oral disease). For ocular or significant oral disease, prednisone (1 mg/kg daily), cyclophosphamide (up to 2.5 mg/kg daily), rituximab (375 mg/m^2 weekly for 4 weeks or 1000 mg given 2 weeks apart), and IVIG (2 g/kg given over 2 to 3 days) may be required under expert supervision.[12]

Mucous membrane pemphigoid is a chronic condition, and untreated ocular disease may lead to blindness.

EPIDERMOLYSIS BULLOSA ACQUISITA

Epidermolysis bullosa acquisita, which is an acquired autoimmune blistering disease, generally occurs in middle age. It can present as noninflammatory acral blisters, which heal with scarring, or as generalized inflammatory vesiculobullous disease. Biopsy shows subepidermal blisters with linear basement membrane IgG deposits that target collagen VII.

TREATMENT

Epidermolysis bullosa acquisita is a chronic condition, and it can be refractory to treatment. Standard treatments, which are only occasionally successful, include colchicine (0.6 mg twice daily), dapsone (up to 200 mg/day), azathioprine (up to 2.5 mg/kg), or cyclophosphamide (2.5 mg/kg/day) alone or combined with prednisone (60 mg daily). For severe or refractory disease, options include cyclosporine (up to 5 mg/kg), rituximab (375 mg/m^2 weekly for 4 weeks or 1000 mg given 2 weeks apart), IVIG (2 g/kg given over 2 to 3 days), plasmapheresis, and extracorporeal photopheresis.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an immune-mediated vesicular disease that occurs by middle age, almost always in patients who have a clinically known or subclinical gluten-sensitive enteropathy (Chapter 126). Skin lesions, which are very pruritic, can be grouped vesicles, papules, or erosions on the scalp, posterior neck, buttocks, and extensor surfaces of the elbows and knees (Fig. 406-14).[13] Many patients have other autoimmune medical conditions, such as diabetes or thyroid disease. Biopsy shows dermal papillary granular IgA deposits and neutrophilic microabscesses. In most patients, circulating IgA antibodies against tissue transglutaminase establish the diagnosis.

TREATMENT

The skin disease can sometimes be controlled by diet alone, but the condition is lifelong. Treatment options also include twice-daily high-potency topical steroids (see Table 403-10) and dapsone (up to 200 mg/day) given chronically.

FIGURE 406-14. Dermatitis herpetiformis. The elbow of a patient has erosions, erythematous papules and vesicles. (Courtesy Daniela Kroshinsky, MD MPH.)

LINEAR IMMUNOGLOBULIN A BULLOUS DERMATOSIS

Linear IgA bullous dermatosis is an acquired autoimmune blistering disease that is usually associated with medications, especially vancomycin. Primary vesicles and bullae develop mainly on the flexural regions, but they can involve the oral mucous membranes and become generalized. Biopsy shows a subepidermal vesicle with neutrophil predominance and linear IgA specific for a portion of bullous pemphigoid antigen II at the basement membrane. Circulating IgA antibodies are detected on indirect immunofluorescence.

TREATMENT

Patients usually respond to cessation of the offending medication and to dapsone (up to 200 mg/day). If the lesions do not respond or rapid control of severe disease is needed, prednisone (1 mg/kg once daily) can be prescribed.

INTRAEPIDERMAL BLISTERING DISORDERS

PEMPHIGUS

Pemphigus refers to a group of intraepidermal autoimmune blistering diseases that affect the skin and mucous membranes.[14] Pemphigus is seen most commonly in middle-age adults.

In *pemphigus vulgaris,* autoantibodies target desmoglein III. In *pemphigus foliaceus,* autoantibodies target desmoglein I. In *paraneoplastic pemphigus,* circulating antibodies react with a complex of proteins, including desmoplakin I and II, desmoglein I and III, bullous pemphigoid antigen I, envoplakin, and periplakin.

With pemphigus vulgaris, patients have flaccid blisters and erosions, which may be pruritic, in the oropharynx (Fig. 406-15), head, neck, and trunk. Patients with pemphigus foliaceus typically have erythema, scaling, and crusting on their scalp, face, and upper torso. Paraneoplastic pemphigus is characterized by ocular and oral blisters and erosions, as well as by polymorphous skin lesions that can resemble lichen planus, erythema multiforme, or pemphigoid. Associated malignancies include non-Hodgkin lymphoma (40%; Chapter 171); chronic lymphocytic leukemia (30%; Chapter 169); Castleman disease (10%; Chapters 171 and 359); thymomas (6%; Chapter 390); sarcomas (6%; Chapter 187); and Waldenström macroglobulinemia (6%; Chapter 173). Some patients can develop severe bronchiolitis obliterans.

In pemphigus vulgaris, biopsy shows suprabasilar acantholysis and deposits of IgG to desmoglein III. In pemphigus foliaceus, biopsy shows subcorneal acantholysis with IgG against desmoglein I. In patients with paraneoplastic pemphigus, biopsy shows suprabasilar acantholysis and dyskeratotic keratinocytes as well as antibodies to plakin proteins and IgG antibodies that are indistinguishable from those seen in pemphigus vulgaris.

TREATMENT

Treatment depends on the subtype and extent of pemphigus, as well as the rate of disease progression and the patient's age. Oral prednisone (e.g., 1 mg/kg once daily) is indicated for the initial treatment of pemphigus vulgaris; topical corticosteroids (e.g., 0.05% fluocinonide ointment applied twice daily to affected areas) sometimes can control pemphigus foliaceus. Adding rituximab (375 mg/m^2 weekly for 4 weeks or 1000 mg IV separated by 2 weeks) to short-term (3 to 6 months) prednisone appears to be safer and more effective than longer-term

prednisone alone,[A1] especially for extensive or recalcitrant disease, and it can induce remission. It is also superior to mycophenolate mofetil (35 to 45 mg/kg/day divided into two daily doses) for controlling the disease but at the expense of more adverse events.[A2] Other steroid-sparing agents for pemphigus vulgaris under expert supervision include azathioprine (up to 2.5 mg/kg), cyclophosphamide (up to 2.5 mg/kg), cyclosporine (3 to 5 mg/kg/day), and methotrexate (up to 25 mg/week). Plasmapheresis has been reported to be efficacious as well.

Systemic treatment of pemphigus foliaceus includes all of these same agents as well as dapsone (up to 200 mg/day) and hydroxychloroquine (total of <6 mg/kg of lean body mass in two divided daily doses). The duration of treatment varies with the level of disease activity.

When paraneoplastic pemphigus is caused by benign tumors, such as Castleman disease,[15] it can often be cured by removing the tumor (Chapter 171). Patients with associated malignant tumors should undergo treatment of their underlying condition but may have recalcitrant disease. Improvement has been reported with pulsed doses of corticosteroids (methylprednisolone, 1000 mg daily for 3 consecutive days) or cyclophosphamide (500 to 1000 mg monthly for 6 months to 1 year, often with varying doses of prednisone), rituximab (four weekly doses of 375 mg/m^2), plasmapheresis, and immunoablative doses of cyclophosphamide (50 mg/kg/day for 4 days).

Morbidity and mortality are related to complications from immunosuppressive therapy. In patients with malignant tumors, the prognosis is generally poor.

FIGURE 406-15. Pemphigus vulgaris—oral involvement. Essentially all patients develop painful oral mucosal erosions. The most common sites are the buccal and palatine mucosae, but lesions can also develop on the gingivae and tongue. (Courtesy Lorenzo Cerroni, MD. From Amagai M. Pemphigus. In: Bolognia JL, Schaffer JV, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:499.)

HYPERSENSITIVITY REACTIONS CAUSING BLISTERS

ERYTHEMA MULTIFORME

Erythema multiforme is a self-limiting hypersensitivity reaction that involves the skin and sometimes mucosal surfaces in response to infection or more infrequently medication.[16] The primary findings are target lesions, which are erythematous to violaceous macules with three zones: two concentric circles and a deeply erythematous to dusky or violaceous center. Target lesions are predominantly concentrated on the distal extremities (Fig. 406-16). The lesions can become bullous or erosive, and in more severe cases erosions occur in the oral, ocular, and/or genital mucosa. The most common infectious causes of erythema multiforme are herpes simplex virus (HSV; Chapter 345) and *Mycoplasma pneumoniae* (Chapter 293) followed by *Histoplasma capsulatum* (Chapter 308).

Biopsy demonstrates nonspecific keratinocyte necrosis, so the diagnosis is clinical.

TREATMENT

Mild cases of erythema multiforme can be treated symptomatically. Severe cases may require systemic corticosteroids (e.g., prednisone 0.5 to 1 mg/kg/day).

Lesions evolve, become fixed for up to 7 days, and then subside within 2 to 3 weeks. Recurrent episodes can occur. For recurrent erythema multiforme due to recurrent HSV, chronic suppressive antiviral treatment with valacyclovir should be considered (Chapter 328).

FIGURE 406-16. Erythema multiforme. Target or "bull's-eye" annular lesions with central vesicles and bullae are characteristic of erythema multiforme. (Courtesy Neil J. Korman, MD.)

FIGURE 406-17. Porphyria cutanea tarda. A blister and erosions are present on the dorsal surface of the hand. (Courtesy Neil J. Korman, MD.)

METABOLIC DISORDERS CAUSING BLISTERS

PORPHYRIA CUTANEA TARDA

Patients with porphyria cutanea tarda (Chapter 194) have skin fragility, painless blisters, and erosions in sun-exposed skin, especially of the face and the dorsal surface of the hands (Fig. 406-17) and the forearms. Healing is associated with scars, atrophic patches, hyperpigmentation, and hypopigmentation. Hypertrichosis is commonly found over the malar and temporal areas.

The cause is loss of activity of uroporphyrinogen decarboxylase (Chapter 194). Porphyria cutanea tarda can be hereditary, owing to a mutation in the *UROD* gene, or it can be acquired, owing to exogenous exposures such as alcohol consumption, hereditary hemochromatosis, hepatitis C, smoking, estrogen use, renal insufficiency, and/or chemical exposure.

Patients with hereditary porphyria cutanea tarda usually present between ages 30 to 50 years, whereas acquired disease usually manifests later. Both forms are associated with iron overload.

Diagnosis is based on elevated urinary porphyrin levels. Biopsy, though not necessary for the diagnosis, shows a minimal dermal infiltrate, subepidermal blistering, and deposition of immunoglobulin and complement at the basement membrane and in dermal capillaries.

TREATMENT

Depending on the type and cause, treatment options (Chapter 194) include avoiding triggers, phlebotomy (titrated so that the serum ferritin level declines to the lower limit of the normal range), hydroxychloroquine (100 mg twice weekly or 200 mg once weekly), or chloroquine (125 mg—half of a 250-mg tablet) orally twice per week until porphyrin excretion remains normal for several months.

PSEUDOPORPHYRIA

Pseudoporphyria, which is similar to porphyria cutanea tarda histologically and clinically but is not seen with any abnormalities of porphyrin, can be associated with chronic renal insufficiency (Chapter 116) or hemodialysis (Chapter 117). It can also occur as a reaction to medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives, furosemide, tetracycline, ciprofloxacin, isotretinoin, amiodarone, cyclosporine, dapsone, isotretinoin, 5-fluorouracil, oral contraceptives, and flutamide. When the offending agent is discontinued, the prognosis is good, but skin lesions may persist or recur for several months.

BULLOSIS DIABETICORUM

Patients with diabetes mellitus (Chapter 210) can develop blisters on their distal extremities. The pathobiology is not understood, and there is no relationship of the skin lesions with the severity, duration, or complications of diabetes. Lesions present spontaneously as large, tense, noninflammatory bulla, often with irregular shapes. Lesions may leave erosions if traumatized. The lesions should be left in place or lanced and drained, leaving the roof in place to serve as a sterile physiologic dressing to reduce the risk of secondary infection. The condition is self-limiting.

INFECTIOUS DISEASES CAUSING BLISTERS

BULLOUS IMPETIGO

Impetigo, which is an epidermal bacterial infection, can be caused by *S. aureus* (Chapter 267) and group A β-hemolytic streptococcus (Chapter 269). Exfoliative toxins A and B target epidermal protein desmoglein 1 and cause cleavage below or within the stratum granulosum. Bullous impetigo presents with superficial vesicles and bulla that easily rupture, thereby resulting in a collarette of scale (Fig. 406-18). Lesions are commonly on the face, trunk, axillae, and perineum. Diagnosis is clinical, with culture of the lesions confirming the causative bacteria.

TREATMENT

Gentle washing is recommended to remove any crusts. Limited cases can be treated with topical 2% mupirocin ointment. Oral antibiotics (e.g., dicloxacillin 500 mg four times daily or cephalexin 500 mg three times daily) for 7 days are indicated for extensive disease and for patients who do not respond to topical antibiotics.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Hematogenous dissemination of exfoliative staphylococcal toxins A and B can result in staphylococcal scalded skin syndrome (Chapter 267). In adults, it is usually seen with renal insufficiency (Chapter 116) or systemic immunosuppression. Patients present with the sudden onset of fever accompanied by blanchable, tender erythema that begins over the face, the neck, and intertriginous areas and then generalizes rapidly. Unlike toxic shock syndrome, the palms, soles, and mucous membranes are not affected. Flaccid blisters, which develop within 1 to 2 days, exfoliate in large sheets and leave behind superficially denuded skin (Fig. 406-19).[17] Skin biopsy can help to distinguish the periorificial fissuring and crusting of staphylococcal scalded skin syndrome from toxic epidermal necrolysis, which causes a subepidermal separation of the skin as well as mucosal involvement.

TREATMENT

Treatment for severe staphylococcal scalded skin syndrome is IV nafcillin or oxacillin 1 to 2 g every 4 hours for 7 to 14 days unless patients have methicillin-resistant staphylococci, in which case they should be treated with IV vancomycin (starting at 1 g every 12 hours, then adjusted based on the creatinine clearance). For mild disease, oral dicloxacillin (500 mg four times daily) for 10 to 14 days is often effective, but methicillin-resistant staphylococci require antibiotics shown to be effective by sensitivity testing.

HERPES SIMPLEX VIRUS INFECTION

Herpes simplex virus (HSV) infection (Chapter 345) commonly presents as a recurrent vesicular eruption on an erythematous base (Fig. 406-20). The location is typically oral and perioral with HSV-1 but genital or sacral with HSV-2.

Traumatized areas may appear as erosions with scalloped borders. Recurrent rash can be precipitated by other infections that suppress the immune system, cold or heat, skin trauma, and menstruation. Immunocompromised patients can develop chronic erosive ulcers.

Tzanck smear from the base of an unroofed vesicle or erosion can be helpful in rapidly confirming the diagnosis by identifying multinucleated giant cells with nuclear molding and margination (see E-Fig. 403-8 in Chapter 403), but the diagnostic "gold standard" is viral culture or direct fluorescent antibody testing. The direct fluorescent antibody test has both high sensitivity and specificity, can yield same-day results, and can distinguish among HSV-1, HSV-2, and varicella-zoster virus (VZV).

TREATMENT

HSV infection is self-limited in healthy individuals. Antiviral treatment with acyclovir, valacyclovir, or famciclovir (see Table 328-4 in Chapter 328) can shorten the initial attack and prevent recurrences. The dose and duration of antiviral therapy depend on whether the infection is disseminated or limited and on whether the patient is immunosuppressed.

VARICELLA

Varicella (chickenpox) caused by VZV (Chapter 346) usually occurs in childhood, but it is more severe when it occurs in adulthood. Erythematous macules on the face, scalp, trunk, and proximal limbs rapidly progress to

FIGURE 406-18. Bullous impetigo. Multiple crusted erosions, flaccid bullae, and pustules are present on the posterior leg of this patient.

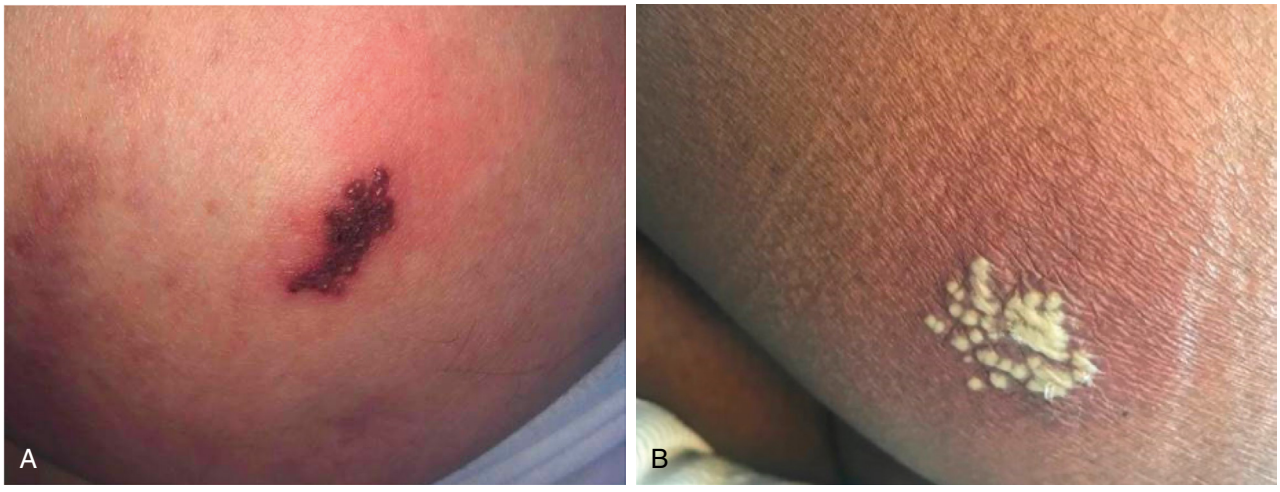

FIGURE 406-20. Recurrent genital herpes. A, Intact grouped vesicles with an erythematous base. **B,** Intact grouped pustules with an erythematous base. (Courtesy Daniela Kroshinsky, MD MPH.)

FIGURE 406-21. Erythematous macules and vesicles with crusted erosions on the chest of a patient with varicella. (Courtesy Neil J. Korman, MD.)

papules, vesicles, pustules, and crusting (Fig. 406-21) 10 to 21 days after exposure. The diagnosis is usually made clinically, with confirmation based on polymerase chain reaction (PCR) testing of the lesion because culture results are often delayed and less sensitive. Tzanck smear can be helpful but cannot distinguish HSV from VZV.

TREATMENT

Immunocompetent adults can be treated with oral valacyclovir (1 g three times daily) or oral acyclovir (800 mg five times daily) for 5 to 7 days with extended courses in cases of delayed crusting and dose adjustments as needed for reduced kidney function. The varicella vaccine is highly effective when given once to children or twice (4 to 8 weeks apart) to previously unvaccinated persons older than 13 years of age (Chapter 15).

HERPES ZOSTER

Herpes zoster (Chapter 346), which is caused by reactivation of VZV from prior primary varicella or following varicella vaccination, most often occurs in individuals who are older or immunocompromised. Patients typically develop grouped vesicles on an erythematous base in a dermatomal distribution (Fig. 406-22). The rash is usually preceded by pain, itching, tingling, or hyperesthesia. Cutaneous dissemination, defined as more than 20 vesicles outside the primary or adjacent dermatomes and/or visceral involvement, more commonly occurs in immunocompromised patients. Dysesthesia in the affected dermatome can persist in up to 20% of patients after resolution of the skin lesions (postherpetic neuralgia). The clinical diagnosis is usually obvious, but PCR testing can be used to confirm it.

FIGURE 406-22. Herpes zoster. A, Necrotic blisters and erosions in a dermatomal pattern are seen on the trunk. (Courtesy Neil J. Korman, MD.) **B,** Crusted herpes zoster of the face. (Courtesy Daniela Kroshinsky, MD MPH.)

TREATMENT

Immunocompetent adults can be treated with valacyclovir (1000 mg three times daily for 7 days), acyclovir (800 mg five times daily for 7 days), or famciclovir (500 mg three times daily for 7 days). In patients who are immunocompromised or have disseminated or visceral disease, intravenous acyclovir (10 mg/kg every 8 hours for 7 to 10 days) is indicated. The initiation of gabapentin with antiviral therapy also can decrease the incidence of postherpetic neuralgia. Varicella vaccination markedly reduces the incidences of both herpes zoster and postherpetic neuralgia (Chapter 346).

PUSTULAR ERUPTIONS

ACNE VULGARIS

Acne vulgaris affects up to 85% of teenagers, but it can persist until adulthood or even develop de novo in adults.[18] The sebum flow, which is stimulated by androgens, is physically impeded by abnormal keratinization in the pilosebaceous canal. The result is the formation of comedones, which can be open to air ("black heads"), or covered by epidermis ("white heads"). Proliferation of *Propionibacterium acnes* within the comedo can lead to rupture of the pilosebaceous unit, with resulting extravasation of its contents into the dermis, thereby creating inflammatory papules, pustules, and nodulocystic lesions.

Acne may be exacerbated or precipitated by oil-based cosmetics, hair preparations, systemic corticosteroids, and androgenic hormones. Other implicated medications include phenytoin, phenobarbital, lithium, and isoniazid. Endocrinologic conditions (e.g., polycystic ovary disease and ovarian or adrenal tumors) also may precipitate or worsen acne.

TREATMENT

Mild disease can be treated with topical benzoyl peroxide,[A3] erythromycin, or clindamycin, and/or a topical retinoid (e.g., adapalene, tretinoin, or tazarotene).[A4] Benzoyl peroxide and topical retinoids can help normalize follicular keratinization, whereas topical antibiotics help control inflammatory papules and pustules. For more serious disease, oral doxycycline or minocycline (50 to 100 mg twice daily) can be helpful.[19] In women, oral contraceptives (containing either ethinyl estradiol plus norgestimate or ethinyl estradiol plus drospirenone) and/or spironolactone can be particularly helpful in the treatment of hormonal acne that can predominantly affect the lower face, jawline, and upper neck. Isotretinoin (1.5 mg/kg given for 5 to 6 months) decreases the size of sebaceous glands as well as their production of sebum and is helpful for resistant disease, severe inflammatory cases, or extensive generalized comedonal involvement.[20]

ROSACEA

Rosacea, which is a chronic inflammatory disease, affects facial pilosebaceous units and blood vessels, generally in middle age.[21] Rosacea is more common in patients who have a tendency toward facial flushing, which can be caused by sun exposure or by other stimuli. (e.g., alcohol, spicy foods, hot liquids, or emotion). The four main types of rosacea are erythematotelangiectatic, papulopustular, phymatous, and ocular. Erythematotelangiectatic rosacea is characterized by persistent central facial erythema and telangiectasias. Papulopustular rosacea is characterized by erythematous papules and pustules in the absence of comedones. Phymatous rosacea is characterized by thickened skin and widened pores, usually of the nose but sometimes of the forehead, chin, ears, and eyelids (Fig. 406-23). Ocular rosacea, is characterized by dry, itchy, or gritty sensation of the eyes, conjunctivitis, blepharitis, and chalazia.

TREATMENT

Avoidance of precipitating causes, especially sun exposure, is recommended for all types of rosacea. Topical antibiotics (e.g., ivermectin 1% cream, azelaic acid 15% gel, or metronidazole 1% cream) are helpful in mild disease,[A5] whereas a low doxycycline dose (20 mg twice daily) is helpful for more inflamed cases.[22] For severe disease, full-dose doxycycline (100 mg twice daily) or minocycline (100 mg twice daily) are efficacious, as is low-dose isotretinoin 0.25 mg/kg.[A6] Ocular rosacea should be managed by an ophthalmologist.

PERIORIFICIAL DERMATITIS

In periorificial dermatitis, patients develop tiny, superficial erythematous papules and papulopustules, accompanied by occasional scaling patches around the mouth, eyes, and nose (Fig. 406-24). Patients often report an intolerance to topical agents and cosmetics, and many have inappropriately used chronic topical corticosteroids. Discontinuation of the corticosteroid often clears the rash, but a 2- to 4-week course of oral antibiotics (e.g., doxycycline 50 to 100 mg twice daily, minocycline 50 to 100 mg twice daily, erythromycin topical or 500 mg twice daily, or azithromycin 500 mg once followed by 250 mg for 4 days administered 2 weeks apart) can also clear the lesions.

ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

Acute generalized exanthematous pustulosis is most frequently caused by antibiotics (especially macrolides and β-lactams), calcium-channel blockers, and antimalarial agents. Edematous erythema and fever typically appear within 2 days after the drug is started, thereby suggesting a prior sensitization to the causative agent. Small sterile pustules subsequently develop on the face or in flexural areas, and they can then disseminate rapidly (Fig. 406-25). Superficial desquamation follows, and the condition usually resolves spontaneously within 2 weeks. Treatment includes discontinuation of the causative agent and the use of bland emollients. Topical corticosteroids (see Table 404-1) can be useful. Management of fluid and electrolyte status may be important in severe cases.

FIGURE 406-23. Rosacea dermatitis. When there is more severe disease, scaling and superficial crusting may be seen as on the cheek of this woman. (Courtesy Kalman Watsky, MD. From Powell FC, Raghallaigh SN. Rosacea and related disorders. In: Bolognia JL, Schaffer JV, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:607.)

FIGURE 406-24. Perioral dermatitis. Erythematous papules and pinpoint pustules are evident around the mouth. (Courtesy Neil J. Korman, MD.)

PUSTULAR PSORIASIS

Pustular psoriasis is a psoriatic variant (Chapter 405) that is triggered by pregnancy, infection, a rapid taper of corticosteroids, hypocalcemia, and medications such as lithium. It can be generalized (Fig. 406-26), localized to the palms and soles, annular, or acute and associated with fever and skin pain. Topical corticosteroids and/or calcipotriene may be sufficient, but systemic cyclosporine or TNF-α inhibitors such as infliximab are often needed for severe cases (Chapter 405).

FOLLICULITIS

Folliculitis, which is inflammation of the hair follicles caused by infection, presents as perifollicular pustules on an erythematous base. The most common cause is staphylococcal infection, but skin flora and gram-negative rods can

FIGURE 406-25. Acute generalized exanthematous pustulosis. Erythematous macules and numerous superficial pustules are present on the trunk of this patient. (Courtesy Neil J. Korman, MD.)

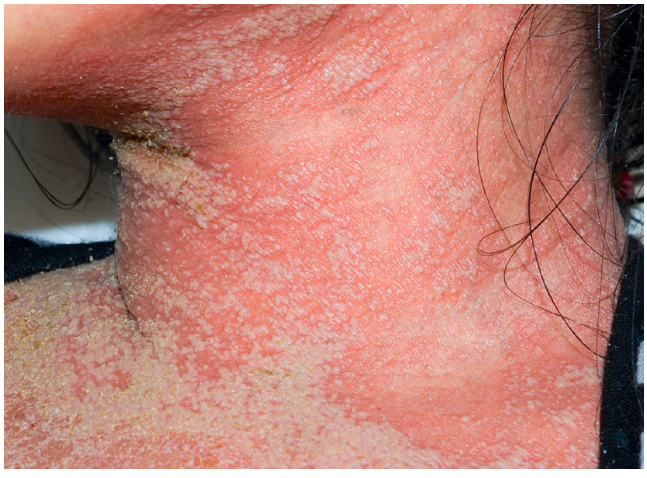

FIGURE 406-26. Generalized pustular psoriasis. Broad areas of erythema with numerous pustules and the formation of lakes of pus. (Courtesy Julie V. Schaffer, MD. From van de Kerkhof PCM, Nestlé FO. Psoriasis. In: Bolognia JL, Schaffer JV, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:145.)

be implicated. In addition, viral (HSV, VZV) and fungal folliculitis can occur. Folliculitis occurs more commonly in patients who are obese, are immunocompromised, or have diabetes mellitus. It most commonly affects follicles of the scalp, axilla, trunk, thighs, and inguinal area, but it also can extend deeper into the dermis where it can cause larger erythematous furuncles or carbuncles. Evaluation includes culture of the pustule's contents or base. Topical antibiotics (e.g., clindamycin solution twice daily for at least 2 weeks) and antibacterial washes (such as with benzoyl peroxide) are useful for mild disease, but antimicrobials (e.g., cephalexin, 500 mg twice daily for 14 days) based on culture results are needed for more extensive infection.

PSEUDOMONAS FOLLICULITIS

Pseudomonas folliculitis manifests 1 to 2 days after using hot tubs or whirlpools contaminated with *P. aeruginosa* (Chapter 282). The typical findings are pruritic papules and pustules, mostly on the torso and accentuated in any skin areas occluded by a bathing suit (Fig. 406-27).[23] The condition is usually self-limited in healthy individuals, but it can be treated with antibacterial soap. Ciprofloxacin (500 mg twice daily for 10 to 14 days) usually cures the infection.

PITYROSPORUM FOLLICULITIS

Pityrosporum ovale folliculitis is a pruritic, acne-like eruption that develops on the face, upper chest, and arms. It is most often seen in young adults, particularly in warm weather, after sweating, and in immunosuppressed individuals. Lesions appear as itchy, follicularly based papules and sometimes pustules over the torso and shoulders. Yeast forms are identifiable on a potassium hydroxide (KOH) preparation. Treatment consists of topical antifungal cream, selenium sulfide shampoo daily for 1 month, or oral itraconazole (200 mg daily for 1 week) or fluconazole (100 to 200 mg daily for 1 to 4 weeks or 300 mg once weekly for 1 to 2 months).

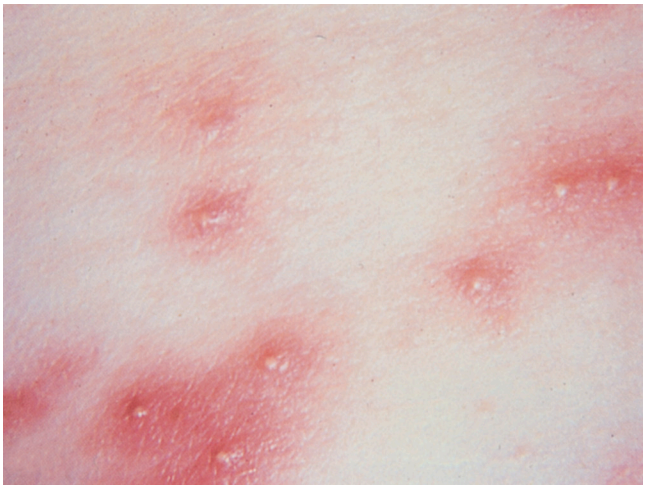

FIGURE 406-27. *Pseudomonas* species folliculitis. The trunk of this patient has numerous pustules on an erythematous base. (Courtesy Neil J. Korman, MD.)

EOSINOPHILIC PUSTULAR FOLLICULITIS

Eosinophilic pustular folliculitis, which is seen in HIV-positive patients, is a sterile but intensely pruritic folliculitis that is usually seen on the face and torso. It is accompanied by peripheral eosinophilia. Skin biopsy demonstrates eosinophils in and around the follicles. Treatment options include antihistamines, topical corticosteroids (see Table 403-10), and topical tacrolimus. Systemic options include indomethacin (50 mg/day), minocycline (100 mg twice daily), dapsone (100 to 200 mg/day), systemic corticosteroids, and colchicine (0.6 mg twice daily). Narrowband ultraviolet B phototherapy also can be helpful.

HIDRADENITIS SUPPURITIVA

Hidradenitis suppurativa, which is a chronic and recurrent inflammatory disease, is characterized by painful, deep-seated nodules and abscesses that result from occlusion of the follicular infundibula followed by inflammation.

Hidradenitis can begin in puberty but most commonly occurs in the early 20s, with its incidence declining substantially after age 50 years. Women predominate over men 3 : 1. The pathogenesis is poorly understood, but it appears to be an inflammatory or immune disease. Cigarette smoking and obesity are risk factors. Biopsy shows atrophy of the sebaceous glands, lymphocytic inflammation of the pilosebaceous unit, destruction of the hair follicles, and granulomas.

The clinical course is chronic, with periods of flares and remissions. The typical presentation is with painful, inflamed nodules and sterile abscesses in the axilla or the groin, but lesions also often occur in the inframammary, genital, and perineal areas. Sinus tracts can develop and be associated with purulent or bloody drainage; lesions may heal with scarring, sometimes cordlike. Flares are often related to menses. Lesions typically recur at the same or nearby sites despite prior incision and drainage and/or oral antibiotics (Fig. 406-28).

TREATMENT

Treatment options have variable success.[24] Weight loss and smoking cessation are encouraged. Moisture reduction through the use of topical aluminum chloride, powders, and loose-fitting clothing can be helpful. Antiseptic soaps and topical antibiotics (e.g., benzoyl peroxide or chlorhexidine washes or topical clindamycin/benzoyl peroxide combination products) may be beneficial for early or mild disease. Intralesional triamcinolone injections can reduce inflammation in early nodules. Systemic therapies include oral antibiotics (doxycycline, minocycline, clindamycin, rifampin, dapsone, trimethoprim-sulfamethoxazole), hormonal therapies (ethinyl estradiol plus cyproterone acetate, spironolactone, finasteride), the phosphodiesterase-4 inhibitor apremilast, TNF-α inhibitors (e.g., adalimumab[A7] 40 mg subcutaneously weekly or infliximab 7.5 to 10 mg/kg intravenously every 4 weeks),[25] and potentially the IgG1k monoclonal antibody secukinumab[A8] (300 mg subcutaneously every 2 to 4 weeks), sometimes combined with wide excision surgery.[A9]

FIGURE 406-28. Hidradenitis suppurativa. The axilla of this patient has several erythematous nodules with draining sinus tracts. (Courtesy Neil J. Korman, MD.)

FIGURE 406-29. Sweet syndrome. The edema can be quite marked as seen in these lesions on the upper back. (Courtesy Kalman Watsky, MD. From Davis MDP, Moschella SL. Neutrophilic dermatoses. In: Bolognia JL, Schaffer JV, Cerroni L, eds. *Dermatology*. 4th ed. Elsevier; 2018:456.)

SWEET SYNDROME

Sweet syndrome is an acute febrile neutrophilic dermatosis characterized by: fever; peripheral neutrophilia; and edematous, painful papules, nodules, or plaques. Sweet syndrome may be idiopathic, but it is more often seen with an underlying condition or exposure to medication.[26] In adults, Sweet syndrome is most commonly associated with hematologic malignancy, especially acute myelogenous leukemia (Chapter 168). It is also seen with inflammatory bowel disease (Chapter 127), infections, pregnancy, and exposure to medications such as all-*trans*-retinoic acid and granulocyte colony-stimulating factor. Sweet syndrome presents clinically with multiple firm, tender, deeply erythematous to violaceous papules, papulovesicles, or nodules, which may turn into edematous plaques. The most common locations are the head, neck, and upper and lower extremities (Fig. 406-29 and Chapter 407) The phenomenon of pathergy, which is the development of inflammatory lesions at sites of dermal injury, may be seen in sites such as IV insertion points and places of venipuncture. When the disease is active, patients may have fever, arthralgias, arthritis, and myalgias as well as a neutrophilic leukocytosis. Biopsy shows superficial edema and a deeper dense neutrophilic infiltrate.

TREATMENT AND PROGNOSIS

The skin lesions respond rapidly to oral corticosteroids (e.g., prednisone, 1 mg/kg/day). Steroid-sparing options include dapsone (100 to 200 mg/day), colchicine (0.6 mg three times daily), and potassium iodide (300 mg three times daily). For refractory disease, options such as cyclosporine, or TNF-α inhibitors may be used by specialists. Recurrent episodes can be a sign of recurrent cancer.

URTICARIA

DEFINITION AND EPIDEMIOLOGY

Urticaria, or hives, is one of the most common cutaneous reaction patterns (Fig. 407-1). It is triggered by a wide variety of antigens or by physical stimuli, including cold, pressure, and sunlight (Table 407-1). Urticaria is a spectrum ranging from simple wheals to angioedema. Clinical distinction between acute and chronic urticaria is important for diagnosis and treatment. Chronic urticaria is defined by recurrence over a period of 6 weeks or more and is often of unknown cause.

Urticaria is common worldwide in persons of all ages, although certain types of urticaria have a predilection for certain age groups. For example, whereas acute urticaria is often seen in children with atopic dermatitis, chronic urticaria peaks in the third and fourth decade.

PATHOBIOLOGY

Urticaria can be caused by immunologic (autoimmune, immunoglobulin E [IgE]–dependent, immune complex–mediated, complement-kinin dependent) or nonimmunologic (direct mast cell–releasing agents, vasoactive stimuli, drugs) reactions. Local degranulation of mast cells with the release of histamine and other factors, such as slow-reacting substance of anaphylaxis, precipitates urticaria. Functional IgE autoantibodies, which release histamine from mast

URTICARIA, DRUG HYPERSENSITIVITY RASHES, NODULES AND TUMORS, AND ATROPHIC DISEASES

MADELEINE DUVIC AND SUSAN Y. CHON

URTICARIA

DEFINITION AND EPIDEMIOLOGY

Urticaria, or hives, is one of the most common cutaneous reaction patterns (Fig. 407-1). It is triggered by a wide variety of antigens or by physical stimuli, including cold, pressure, and sunlight (Table 407-1). Urticaria is a spectrum ranging from simple wheals to angioedema. Clinical distinction between acute and chronic urticaria is important for diagnosis and treatment. Chronic urticaria is defined by recurrence over a period of 6 weeks or more and is often of unknown cause.

Urticaria is common worldwide in persons of all ages, although certain types of urticaria have a predilection for certain age groups. For example, whereas acute urticaria is often seen in children with atopic dermatitis, chronic urticaria peaks in the third and fourth decade.

PATHOBIOLOGY

Urticaria can be caused by immunologic (autoimmune, immunoglobulin E [IgE]–dependent, immune complex–mediated, complement-kinin dependent) or nonimmunologic (direct mast cell–releasing agents, vasoactive stimuli, drugs) reactions. Local degranulation of mast cells with the release of histamine and other factors, such as slow-reacting substance of anaphylaxis, precipitates urticaria. Functional IgE autoantibodies, which release histamine from mast

ABSTRACT

Urticaria, or hives, is the most common cutaneous reaction pattern. The pink to light red blanching lesions are raised and pruritic. Management depends on the severity and duration of symptoms. For recurrent chronic spontaneous urticaria, cyclosporine or omalizumab therapy can be very effective. Drug rashes include rashes with eosinophilia, erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, leukocytoclastic vasculitis, drug eruptions, and contact dermatitis. Benign papules include actinic keratoses, seborrheic keratoses, and warts. Each of these lesions must be carefully diagnosed so that an effective topical and sometimes systemic therapy can be prescribed.

TABLE 407-1 COMMON CAUSES OF URTICARIA

URTICARIA MAY BE ACCOMPANIED BY ANGIOEDEMA AND ANAPHYLAXIS
Blood products: red blood cells, platelets, gamma globulin
Drugs
Antibiotics: penicillins, cephalosporins, sulfonamides, isoniazid
Aspirin: salicylates, benzoates, phenylbutazone
Anticonvulsants: hydantoin
Chemotherapy: doxorubicin, daunorubicin, L-asparaginase, chlorambucil, cyclophosphamide, melphalan, methotrexate, nitrogen mustard, procarbazine
Dextran
Nonsteroidal anti-inflammatory drugs
Opiates
Quinidine
Radiocontrast dyes, iodine
Environmental: animal dander or proteins, formaldehyde, pollen, mold, plants, latex, plastic tubing, exercise, heat, cold, sunlight, dermal vibration
Foods: berries, eggs, milk, nuts, tomatoes, shellfish, soy
Food additives: sodium benzoate, tartrazine (yellow dye #5)
Hormones
Infections: streptococcal, staphylococcal, sinusitis or abscesses, viral hepatitis, Epstein-Barr virus mononucleosis, *Candida* spp
Insect bites or venom: Hymenoptera, mosquitoes, mites, scabies, bed bugs
Mechanical stimuli (dermographism, vibratory angioedema, delayed-pressure urticaria)
Vaccines
URTICARIA-LIKE ERUPTIONS AND REACTIVE ERYTHEMAS
Erythema multiforme: herpes simplex, DNA viruses, *Mycoplasma pneumoniae,* drugs
Erythema marginatum: streptococcal rheumatic fever
Juvenile rheumatoid arthritis
Erythema chronicum migrans: *Borrelia* spp infections
Erythema annulare centrifugum: tinea, drugs
Figurate erythemas: erythema repens (often with underlying carcinoma)
Urticaria pigmentosa (mastocytosis)

spp = species.

cells and basophils, are commonly found in the blood of patients with chronic urticaria. Additionally, basophils are recruited into the wheals, where they sustain the response by releasing histamine. Eosinophils also contribute through leukotriene C_4 (LTC_4), leukotriene D_4 (LTD_4), leukotriene E_4 (LTE_4), and major basic protein. Urticaria is typically transient and self-limited, without leakage of blood cells into the skin or damage to the blood vessels. Leakage of plasma into the dermis from capillaries and small postcapillary venules correlates clinically with development of a demarcated, pink, raised lesion (hive).

CLINICAL MANIFESTATIONS

Urticarial lesions are pink to light red, blanch with pressure, and are raised above the surface of the skin. The center of the lesions may be paler than the leading edge. By definition, an individual hive persists for less than 24 hours. A mosquito bite (Chapter 233) is the archetypal urticarial lesion. Individual hives can coalesce into giant plaques or annular rings, and in serum sickness they can be accompanied by arthralgias and fever. Confluent urticaria also may be accompanied by swelling of the underlying soft tissue or the mucous membranes (angioedema). Anaphylaxis with laryngeal edema is a life-threatening emergency. In otherwise normal individuals, pressure, scratching, or vibration on the skin will cause spontaneous local release of histamine, which induces a wheal-and-flare reaction or dermatographism. Deep swelling from sustained pressure may remain for days in delayed pressure urticaria. Affected individuals may develop lesions from tight-fitting clothing, shoes, socks, watches, or sexual intercourse.

Cold, heat, sun, pressure, or exercise may also induce urticaria. Cold urticaria may be precipitated by putting an ice cube on the skin; the interval until hives develop and the duration of the hives correlate with the severity of the condition. Cold urticaria can be life threatening if the patient is suddenly immersed in cold water. Heat, exercise, or exertion may be accompanied by small, 2- to 3-mm urticarial lesions in a condition called cholinergic urticaria. Exercise-induced anaphylaxis may be hereditary, but the defect is unknown. Patients with vibratory angioedema develop swelling and erythema within a few minutes of exposure to a vibratory stimulus. Lesions persist for about 30 minutes. Other forms of physically induced urticaria include solar urticaria and aquagenic urticaria (urticarial lesions caused by exposure to sun and water, respectively).

Food and exercise–induced anaphylaxis is a syndrome in which a few minutes of exercise after ingestion of specific foods results in angioedema or anaphylaxis. The cause of this syndrome is still controversial, but reduced gastric acid secretion may be involved in food and exercise–induced anaphylaxis.

DIAGNOSIS

A detailed history (e.g., duration, occupation, prescribed medications, over-the-counter supplements, frequency of episodes, associated illness) is critical. Urticaria typically results from exposure to antigen only minutes to a few hours before the onset of the lesions. In many cases, pruritus may precede onset of the rash. The most common triggers of IgE-mediated allergic urticarial reactions are drugs (especially penicillin, sulfa drugs, antibiotics, and contrast dye), foods (shellfish, salicylates in berries, tomatoes, yeast, and penicillin in blue cheese), food additives (sodium benzoate), nuts (especially peanuts), latex, and insect bites. Nonimmunologic mediators of urticaria include aspirin and opiates as well as physical agents that work through the prostaglandin pathway or degranulate mast cells.

Acute urticaria also can be triggered by skin contact with an antigen, such as latex, and can progress to anaphylaxis. In addition, urticaria can be a sign or prodrome of a latent infection, especially streptococcal pharyngitis in children or viral hepatitis in adults. The migratory urticarial rash accompanying rheumatic fever, erythema marginatum (Fig. 407-2), is characterized by evanescent, scalloped lesions that change location over the course of hours.

When urticarial lesions are present for more than 24 hours, underlying urticarial vasculitis should be suspected. A skin biopsy is required to distinguish urticarial vasculitis from urticaria in which no damage to the blood vessels is evident. When vascular damage is present, the lesion is termed *leukocytoclastic vasculitis*, the most severe expression of hypersensitivity reactions involving cutaneous blood vessels.

Chronic urticaria can be caused by occult infections (sinusitis, gallbladder disease, *Helicobacter pylori*, yeast infections, tooth abscesses, or silent hepatitis) as well as by collagen vascular diseases and tumors, especially Hodgkin lymphoma. Deficiency of the C1 esterase inhibitor can cause chronic urticaria with angioedema. Allergy testing is recommended if the history is unrevealing. If lesions persist for more than 24 hours, skin biopsy is indicated to determine whether vasculitis or mastocytosis is present (see Fig. 232-4). If infection, collagen vascular disease, or a tumor is suspected, a full serologic evaluation should be undertaken. Although a thorough medical evaluation may aid in diagnosis, the cause of chronic urticaria may remain uncertain. In the absence of a known antigen, stress is often invoked as the underlying cause of chronic recurrent idiopathic urticaria.

Systemic mastocytosis[1] (Chapter 235) may be accompanied by urticarial lesions and gastrointestinal symptoms. In the form of mastocytosis known as *urticaria pigmentosa*, stroking the lesions produces urticaria, known as the *Darier sign*. A skin biopsy shows an increased number of dermal mast cells. Serum tryptase and histamine levels may be elevated during an attack.

TREATMENT

Management of urticaria depends on its severity and the duration of the problem[2] (Chapter 232). For mild urticaria limited to the skin, traditional oral antihistamines (diphenhydramine) or the newer nonsedating agents (terfenadine, cetirizine, loratadine) can be administered intermittently as needed (Table 407-2).[A1] Acute urticaria is often treated with diphenhydramine orally. If the urticaria is severe, short-term corticosteroids, up to 1 mg/kg, can be used, but their efficacy is uncertain.[A2] For urticaria associated with wheezing or anaphylaxis, subcutaneous epinephrine, intravenous (IV) corticosteroids, and oxygen should be administered immediately.

Finding the cause and removing the antigen of chronic recurrent urticaria is highly preferable to chronic administration of corticosteroids or antihistamines. The patient should avoid aspirin compounds, nonsteroidal anti-inflammatory drugs (NSAIDs), and other drugs that could be the cause.

For chronic spontaneous urticaria that persists, omalizumab, an anti-IgE monoclonal antibody at 300 mg subcutaneously once per month,[A3] or cyclosporine (at doses of 3 mg/kg or higher for 8 to 16 weeks), is effective in 65 to 70% of patients who do not respond to H_1-antihistamines (Chapter 232). Prednisone is to be avoided because of long-term toxicity.

TABLE 407-2 TREATMENT OF URTICARIA

1. Avoid the inciting agent!
2. Medications based on severity
   - A. Mild to moderate, acute urticaria
     - Oral H_1-antihistamines (e.g., diphenhydramine, 25-50 mg PO q4-6h, or hydroxyzine, 10-25 mg PO q6h; nonsedating alternatives include cetirizine, 5-10 mg/day, levocetirizine 2.5-5 mg/day, fexofenadine 180 mg/day, or loratadine, 10 mg/day)
     - Omalizumab (an anti-IgE antibody) 150-300 mg subcutaneously monthly
   - B. Severe urticaria with or without angioedema
     - H_1-antihistamines (e.g., diphenhydramine, 25-50 mg PO q4-6h or 10-50 mg IV/IM q4-6h, not to exceed 400 mg/24 hr)
     - Corticosteroids (e.g., prednisone, 10-60 mg PO every morning with tapering over a 2-wk period; triamcinolone 40-60 mg IM for one dose; or dexamethasone, 4-20 mg/day IV/IM for one dose or divided doses q6-12h, depending on severity)
   - C. Anaphylaxis
     - A—Airway (intubation)
     - B—Breathing (oxygen)
     - C—Circulation: parenteral aqueous epinephrine, 1 : 1000 IV, saline or volume expanders
     - IV corticosteroids (e.g., methylprednisolone, 1-2 mg/kg/day; see Chapter 233)
     - Histamine H_1- and H_2-antagonists (diphenhydramine 25-50 mg IV and famotidine 20 mg IV; see Chapter 233)
   - D. Chronic idiopathic urticaria—combination therapy
     - Nonsedating PO H_1-antihistamine: cetirizine, 10 mg/day, or fexofenadine, 60-180 mg once or twice daily, alone or with leukotriene receptor antagonist: montelukast, 10 mg/day, or H_1 and H_2 antagonists (famotidine 20 mg twice daily or cimetidine 400 mg twice daily) and/or low-dose corticosteroids (if unavoidable)
     - Omalizumab (anti-IgE monoclonal antibody) at 150-300 mg subcutaneously once monthly and cyclosporine (doses of 3 mg/kg/day or higher for 8-16 weeks)

Ig = immunoglobulin; IM = intramuscularly; IV = intravenously; PO = orally.

FIGURE 407-2. Erythema marginatum. (From Medscape. Urticaria; n.d. http://www.medscape.com/content/1998/00/41/73/417394/art-m5649.fig2.jpg. http://www.dermnetnz.org/reactions/urticaria.html. Accessed October 23, 2014.)

DRUG RASHES

DEFINITION

Drugs have been associated with every type of cutaneous reaction pattern ranging from mild and self-limited to severe and life-threatening. Urticaria and exanthematous eruptions are common manifestations of cutaneous drug reactions. Less commonly seen are fixed drug, lichenoid, pustular, phototoxic, bullous, or vasculitic reactions, and the spectrum of erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

PATHOBIOLOGY

Drug rashes, which result from drug toxicity, overdose, drug-drug interactions, or products of metabolism, may be caused by immunologic or nonimmunologic mechanisms. Drugs or their metabolites can act as haptens and induce cell-mediated or humoral responses. Mechanisms include IgE-dependent anaphylaxis and urticaria, cytotoxic reactions resulting in thrombocytopenia and resultant petechiae, immune complex–mediated serum sickness, and delayed-type hypersensitivity resulting in exanthematous or fixed drug eruptions or Stevens-Johnson syndrome.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Drug rashes are either immediate (urticaria) or delayed hypersensitivity reactions (exanthems). Immediate reactions such as pruritus, hives, angioedema, and anaphylaxis occur within minutes to a few hours after the drug is taken. The most common drug-related rash (Table 407-3) is a $CD8^+$ T-cell–mediated hypersensitivity reaction manifested as a macular, bright pink to salmon–colored exanthem that appears as early as 7 to 10 days and as late as 14 days after a drug is first administered. Delayed hypersensitivity reactions can be macular or papular exanthems (or both), morbilliform eruptions, annular erythema, or confluent erythema (Fig. 407-3). After sensitization to a particular drug has occurred, readministration of the same drug may trigger an eruption within 24 to 72 hours. Drug hypersensitivity reactions are typically symmetrical. They characteristically begin on the face and upper trunk and progress to the lower extremities, where they may become purpuric. Exanthems secondary to drugs most often become confluent erythematous patches after several days.[3]

Pruritus is the most common symptom. The differential diagnosis for drug rashes includes viral exanthems (Chapter 406), graft-versus-host disease or the leukocyte recovery rash after allogeneic bone marrow transplantation, erythematous exanthems that accompany streptococcal (scarlet fever [Chapter 269]) or staphylococcal (toxic shock syndrome [Chapter 267]) infections, and the acute manifestation of collagen vascular diseases. A similar exanthem occurs when ampicillin is administered to patients who have infectious mononucleosis. A careful drug history is critical in diagnosis and treatment.

TREATMENT AND PROGNOSIS

After the offending drug is discontinued, delayed hypersensitivity reactions resolve in about 1 week. Therapy is mostly supportive. Corticosteroids, such as triamcinolone 0.01% cream applied several times per day to the affected area and antihistamines given orally three to four times daily are helpful in reducing the itching and shortening the course.

SPECIFIC SYNDROMES

DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS

Drug-induced hypersensitivity rash and drug-induced hypersensitivity syndrome/drug reaction with eosinophilia and systemic symptoms (DRESS) is most frequently seen with sulfonamides and anticonvulsant medications[4] (Fig. 407-4). This condition is thought to be caused by an alteration in drug metabolism. Activated T lymphocytes release interleukin-5 (IL-5), leading to characteristic eosinophilia. DRESS involves activation of human herpes virus-6 and sometimes other DNA viruses. In some patients, there can be an overlap with cutaneous T-cell lymphoma or mycosis fungoides.

Eosinophilia and its systemic symptoms set DRESS apart from the usual delayed hypersensitivity drug rashes. DRESS may be delayed in onset by 2 to 6 weeks, persists longer than classic drug-induced eruptions, and becomes

TABLE 407-3 DELAYED HYPERSENSITIVITY DRUG RASHES BY CATEGORY

MACULOPAPULAR EXANTHEMS—ANY DRUG CAN PRODUCE A RASH 7-10 DAYS AFTER THE FIRST DOSE
Allopurinol Antibiotics: penicillin, sulfonamides Antiepileptics: phenytoin, phenobarbital Antihypertensives: captopril, thiazide diuretics Contrast dye: iodine Gold salts Hypoglycemic drugs Meprobamate Phenothiazines Quinine
DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS (DRESS)
Anticonvulsants: phenytoin, phenobarbital, valproate, lamotrigine Antibiotics: sulfonamides, minocycline, dapsone, ampicillin, ethambutol, isoniazid, linezolid, metronidazole, rifampin, streptomycin, vancomycin Antihypertensives: amlodipine, captopril Antidepressants: bupropion, fluoxetine Allopurinol Celecoxib Ibuprofen Phenothiazines
ERYTHEMA MULTIFORME/STEVENS-JOHNSON SYNDROME/TOXIC EPIDERMAL NECROLYSIS SPECTRUM
Sulfonamides, phenytoin, barbiturates, carbamazepine, allopurinol, amikacin, phenothiazines Toxic epidermal necrolysis: same as for erythema multiforme but also acetazolamide, gold, nitrofurantoin, pentazocine, tetracycline, quinidine
ACUTE GENERALIZED EXANTHEMIC PUSTULOSIS (AGEP)
Antibiotics: penicillins, macrolides, cephalosporins, clindamycin, imipenem, fluoroquinolones, isoniazid, vancomycin, minocycline, doxycycline, linezolid Antimalarials: chloroquine, hydroxychloroquine Antifungals: terbinafine, nystatin Anticonvulsants: carbamazepine Calcium-channel blockers Furosemide Systemic corticosteroids Protease inhibitors
COLLAGEN VASCULAR OR LUPUS-LIKE REACTIONS
Procainamide, hydralazine, phenytoin, penicillamine, trimethadione, methyldopa, carbamazepine, griseofulvin, nalidixic acid, oral contraceptives, propranolol
ERYTHEMA NODOSUM
Oral contraceptives, penicillin, sulfonamides, diuretics, gold, clonidine, propranolol, opiates Fixed drug reactions: phenolphthalein, barbiturates, gold, sulfonamides, meprobamate, penicillin, tetracycline, analgesics

generalized and severe even when use of the agent is discontinued.[§] It typically begins as a morbilliform eruption, which later evolves into an edematous pustular eruption with erythroderma and purpura. The rash begins on the face, upper trunk, and extremities and later becomes generalized. Continued administration of the drug can result in exfoliative erythroderma; toxic necrolysis; and systemic hypersensitivity, including hepatitis (50%), nephritis (10%), or atypical lymphocytosis and lymphadenopathy mimicking mononucleosis or T-cell lymphoma. Less commonly seen are pneumonitis, myocarditis, and pericarditis. With visceral involvement, there is a 10% mortality rate, usually from hepatic failure.

TREATMENT

The initial step in management is the immediate withdrawal of the suspected drug. Systemic corticosteroids (e.g., oral prednisone at 1.0 mg/kg/day and tapered over 2 to 3 months) should be started as early as possible. For patients who develop exfoliative dermatitis, admission to a specialized unit such as a burn unit or intensive care unit is critical.

ERYTHEMA MULTIFORME, STEVENS-JOHNSON SYNDROME, AND TOXIC EPIDERMAL NECROLYSIS

Stevens-Johnson syndrome and toxic epidermal necrolysis represent a spectrum of the same disease, of which erythema multiforme (see Fig. 406-16 in Chapter 406) is the least severe, with less than 10% body surface area involvement. Intermediate involvement of 10 to 30% is called Stevens-Johnson syndrome, whereas toxic epidermal necrolysis is defined by extensive skin necrosis on greater than 30% of the body surface area.

Drugs (e.g., sulfonamides, seizure medications, NSAIDS, allopurinol, nevirapine, and chlormezanone) are almost always implicated when Stevens-Johnson syndrome or toxic epidermal necrolysis develops in adults (Fig. 407-5). The risk is also increased in patients infected with the human immunodeficiency virus.

The mildest form (erythema multiforme) is a hybrid of urticaria and vasculitis and consists of symmetrically distributed red macules or papules that

FIGURE 407-3. Morbilliform drug eruption due to trimethoprim-sulfamethoxazole (TMP-SMZ). This human immunodeficiency virus (HIV)–positive young man developed a widespread eruption of blanchable erythematous macules and papules 8 days after starting TMP-SMZ. Note the coalescence on the upper trunk. (From Bolognia. *Dermatology*, 4th ed.)

FIGURE 407-4. Hypersensitivity drug rash caused by phenytoin.

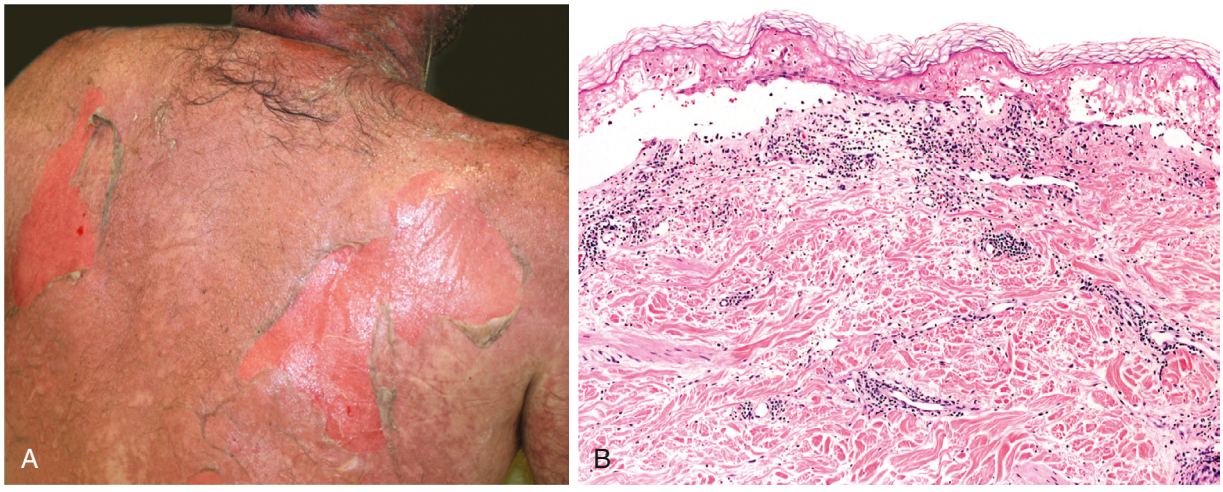

FIGURE 407-5. Toxic epidermal necrolysis. A, Detachment of necrolytic epidermis, leading to large areas of denuded skin. The glistening areas are exposed dermis. **B,** Full-thickness epidermal cell death results in a subepidermal separation. The normal stratum corneum points to the acute nature of the disease process. In the dermis, there is a lymphohistiocytic inflammatory infiltrate admixed with a few eosinophils. (From Bolognia. *Dermatology*, 4th ed.)

evolve into classic target or bull's-eye lesions with deep red centers and pink urticarial rims. Erythema multiforme is commonly precipitated by herpes simplex infections, other DNA viruses, or drugs.

Stevens-Johnson syndrome is characterized by flu like prodrome followed by development of characteristic flat hemorrhagic lesions on the mucosal membranes, trunk, and extremities. In toxic epidermal necrolysis, full-thickness keratinocyte necrosis or cell apoptosis leads to separation at the dermal-epidermal junction.[6] In the active phase of toxic epidermal necrolysis, skin blisters and erosions can be accompanied by pulmonary and hepatic involvement.

Each of these conditions may start as a morbilliform hypersensitivity drug rash and progress to skin necrosis. Symptoms include fever, severe pain, or sometimes asthenia. These conditions can progress rapidly, so it is critical to determine and discontinue the causative agent immediately.

TREATMENT

Management includes supportive care such as fluid and electrolyte replacement, transfer to a burn unit, wound care, treatment of infection, and ophthalmologic evaluation. Corticosteroids (e.g., IV methylprednisolone at 60 mg every 6 hours or 1 to 2 mg/kg for a short course) are frequently given, and IV immunoglobulin may decrease the duration of fever and slow eruptions.[7] Based on observational data, tumor necrosis factor–α inhibitors (e.g., etanercept) and cyclosporine (3 to 5 mg/kg per day) may be beneficial under the direction of a specialist.[8] Erythema multiforme can be inhibited by the chronic administration of oral acyclovir (400 mg twice daily).

PROGNOSIS

In toxic epidermal necrolysis, skin ulceration can lead to systemic sepsis (Chapter 94). Superinfection and fluid and electrolyte imbalances can lead to death in 5% of cases of Stevens-Johnson syndrome and 30% of cases of toxic epidermal necrolysis. Predictors of poor outcomes include older age, malignancy, and renal failure.

LEUKOCYTOCLASTIC VASCULITIS

Severe drug reactions can also be manifested as vasculitis, neutrophilic eruptions, and ulcerations. Vasculitis is further categorized by the size of the involved vessel and the nature of the cellular reaction and immune complexes. Leukocytoclastic vasculitis, which is the most common form of vasculitis induced by drugs, is manifested as palpable purpura, usually on the lower extremities (see Figs. 406-4 and 406-5 in Chapter 406).

NEUTROPHILIC DRUG REACTIONS

Neutrophilic drug reactions include iododermas, bromodermas, acute generalized exanthematous pustulosis, and acneiform folliculitis. Sweet syndrome (acute febrile neutrophilic dermatosis; see later) also can be drug related. Epidermal growth factor receptor inhibitors and protein kinase inhibitors cause an acneiform facial or chest eruption that is associated with drugs (Fig. 407-6).

FIGURE 407-6. Epidermal growth factor receptor inhibitor–associated rash.

Acute generalized exanthematous pustulosis is characterized by numerous (>100), small (<5 mm), nonfollicular subcorneal pustules that arise on erythematous skin, often beginning in skin creases or on the face. High fever and peripheral neutrophilia may precede or accompany the eruption. The pustules are sterile, present for 5 to 10 days, and followed by desquamation. They usually appear less than 2 days after the administration of the causative drug. Ninety percent of cases are due to drugs, most commonly β-lactam antibiotics, macrolides, and calcium channel blockers. This syndrome also has been called pustular drug rash, pustular psoriasis after corticosteroid withdrawal, and toxic pustuloderma. When severe, it may be confused with toxic epidermal necrolysis, but the mortality rate is only 1 to 2%. Skin patch testing is frequently positive.

FIXED DRUG ERUPTIONS

A fixed drug reaction appears at the same location 1 to 2 weeks after first drug exposure and within 24 hours of repeat exposure. The lips, hands, face, feet, and genitalia are most commonly involved. The lesion may begin as erythema and then become gray, brown, or violaceous. Trimethoprim-sulfamethoxazole, NSAIDs, tetracyclines, and pseudoephedrine are common causes.[9]

PHOTOSENSITIVITY AND WITHDRAWAL REACTIONS

Light combined with drugs (Table 407-4) can produce photosensitivity reactions that can be quite severe and mimic sunburn. Ultraviolet radiation interacts with a drug or its metabolite to generate reactive oxygen species, leading to cellular damage. Tetracyclines, sulfa drugs, NSAIDs, and fluoroquinolones are often implicated in photosensitivity reactions. Photosensitizing drugs may exacerbate lupus erythematosus (Chapter 245) or porphyria cutanea tarda (Chapter 194).[10]

TABLE 407-4 DRUGS ASSOCIATED WITH SUN SENSITIVITY

PHOTOTOXIC
Chlorpromazine
Hydralazine
Levaquin
Procainamide
Psoralens
Porphyrins
Sulfonamides
Tetracyclines
Thiazide diuretics
PHOTOALLERGIC
Chlorothiazide
Griseofulvin
Hypoglycemic drugs
Promethazine

CONTACT DERMATITIS

Allergic contact dermatitis is a T-cell–mediated delayed hypersensitivity reaction that occurs after topical drug application or exposure to poison ivy, oak, or sumac.[11] It is manifested by erythema and microvesiculation and may spread beyond the area of application (id reaction). Common contact sensitizers include Neosporin (polymyxin B, neomycin, and bacitracin), bacitracin, diphenhydramine, doxepin, lidocaine, lanolin, mercury, henna, ethyl cyanoacrylate (eyelash adhesive), nickel, hair dyes, latex, and *p*-aminobenzoic acid.

BENIGN PAPULES, NODULES, AND TUMORS

The skin is heterogeneous, composed of epidermis, dermis, subcutaneous compartments, and blood vessels. The skin hosts a number of migrating cells (Chapter 403), all of which can give rise to benign or malignant tumors. Lesions that arise from epidermal keratinocytes are usually papules (actinic keratoses, warts, seborrheic keratoses) or plaques (psoriasis, Bowen disease). Nodules are deeper dermal lesions that may be tender or asymptomatic and single or multiple, and they break down to form ulcers. Nodules are classified as inflammatory (granulomas, vasculitis, or panniculitis), infectious, vascular, metabolic, or neoplastic. Nodules can be benign or malignant tumors that arise from skin cells or migrant cells (Table 407-5). Nodules that are smaller and symmetrical are more likely to be benign than lesions that grow rapidly, are larger, or invade surrounding tissue. Any rapidly changing skin nodule should be investigated with an excisional biopsy to the level of fat and sent for histology as well as for bacterial, fungal, and acid-fast cultures.

BENIGN EPIDERMAL TUMORS

The top layer of skin is the avascular epidermis composed of keratinocytes that undergo apoptosis, thereby forming the stratum corneum. Melanocytes, Langerhans cells, and inflammatory cells may enter the epidermis. Epidermal stem cells form adnexal organs such as hair follicles and sebaceous, eccrine, and apocrine glands that can give rise to tumors.

ACTINIC KERATOSES

Actinic keratoses are pink, scaly macules composed of sun-damaged keratinocytes and are precursors of in situ squamous cell carcinomas (Bowen disease) or invasive squamous carcinomas (Chapter 188). Actinic keratoses are 0.1 cm to 1.0 cm in size and are found on sun-exposed areas such as the forearms, hands, face, and scalp (Fig. 407-7). Lesions with induration, thick crusts, ulceration, or pain should be excised for biopsy to exclude invasive squamous cell carcinoma.

TREATMENT

Tirbanibulin 1% ointment applied once daily for 5 days can result in complete clearance in about 50% of patients, but about 50% of responders will develop recurrent lesions in the next year.[A4] Other options include photodynamic therapy with topical aminolevulinate, cryotherapy, topical fluorouracil, retinoids, imiquimod, or ingenol mebutate gel.[A5–A8] To treat and prevent actinic keratoses, sun-exposed areas may be treated topically with 5-fluorouracil cream (5%) applied twice a day for 2 weeks or twice weekly for 8 weeks.[12] If needed, topical mupirocin ointment can used to prevent staphylococcal infection.

TABLE 407-5 TUMORS AND NODULES OF THE SKIN

Benign, nonpigmented tumors and nodules
Epidermal: warts, acrochordons, tricholemmomas, sebaceous hyperplasia
Adnexal: epidermal cysts, syringomas, follicular cysts, pilomatricoma, pilar cysts, apocrine or eccrine adenomas
Dermal and subcutaneous: lipomas, angiolipomas, neurofibromas, leiomyomas
Benign, pigmented tumors and nodules
Epidermal: seborrheic keratoses
Melanocytic compound nevi (junctional nevi are flat)
Spitz nevus
Blue nevus
Dermatofibromas
Malignant, nonpigmented tumors and nodules
Basal cell carcinoma (nodular, superficial, morpheaform, pigmented)
Squamous cell carcinoma (actinic keratoses, Bowen disease, keratoacanthomas)
Cutaneous T- and B-cell lymphomas
Amelanotic melanomas
Merkel cell carcinomas
Adnexal carcinomas of the sebaceous and/or apocrine glands
Malignant, pigmented tumors and nodules
Pigmented basal cell carcinoma
Malignant melanoma: in situ, superficial spreading, nodular, acral lentiginous
Dermatofibrosarcoma protuberans
Inflammatory nodules over joints
Gottron papules (dermatomyositis)
Gouty tophi
Heberden nodes (osteoarthritis)
Multicentric reticulohistiocytosis (paraneoplastic syndrome)
Rheumatoid nodules
Granuloma annulare
Inflammatory nodules of the lower extremities
Panniculitis
Vasculitis: periarteritis nodosa
Metabolic nodules of the skin
Amyloidosis
Gouty tophi
Xanthomas, necrobiotic xanthogranuloma
Xanthelasma
Vascular lesions
Benign: nevus flammeus, angiokeratomas, spider hemangiomas, capillary hemangiomas, cavernous hemangiomas, blue rubber bleb nevi, pyogenic granulomas
Malignant: Kaposi sarcoma, angiosarcoma

SEBORRHEIC KERATOSES

Seborrheic keratoses are common verrucous or stuck-on epidermal papules and plaques of various colors (Fig. 407-8).[13] They are common with advancing age, but a sudden eruption of seborrheic keratoses may be indicative of an internal malignancy. Seborrheic keratoses consist of a single clone of keratinocytes and are inherited as an autosomal dominant trait. Seborrheic keratoses have *FGFR3, PIK3CA, KRAS, EGFR, HRAS,* and *AKT* mutations but remain clinically benign. Their surface may be friable, and lesions can be scraped off. Seborrheic keratoses spare the palms, soles, and mucosal surfaces. Although benign, seborrheic keratoses must be differentiated from melanocytic nevi, melanomas, and pigmented basal cell carcinoma, usually by the presence of white to yellow horn cysts on their surface, best appreciated with dermoscopy. If needed, treatment options include cryotherapy, curettage, shave excision, or laser excision.[A9]

WARTY LESIONS

Epidermal papules include common warts (see Fig. 406-3 in Chapter 406) caused by human papillomavirus (HPV). HPV also can be detected in squamous carcinomas arising on the digits and in keratoacanthomas, which are low-grade, well-demarcated, dome-shaped papules or nodules that grow rapidly and spontaneously involute in 6 to 8 weeks. Acrodermatitis verruciformis is characterized by multiple warts with the appearance of seborrheic keratoses on the dorsal extremities and gives rise to squamous cell carcinomas. Molluscum contagiosum (Chapter 343) (Fig. 407-9), caused by a DNA virus, are small, shiny, domed-shaped, 1- to 5-mm papules with a central depression. Molluscum contagiosum lesions are common in children and immunocompromised patients. Treatment with anticancer BRAF inhibitors can cause warty papules, keratoacanthomas, and eruptive keratosis pilaris.

Cowden syndrome (Chapter 179), caused by mutations in the *PTEN* gene, is associated with warty papules (tricholemmomas; Fig. 407-10); cobblestone

FIGURE 407-7. Actinic keratoses. Numerous hypertrophic actinic keratoses on the bald scalp, with hypopigmentation at sites of previous treatment. (From Bolognia. *Dermatology*, 4th ed.)

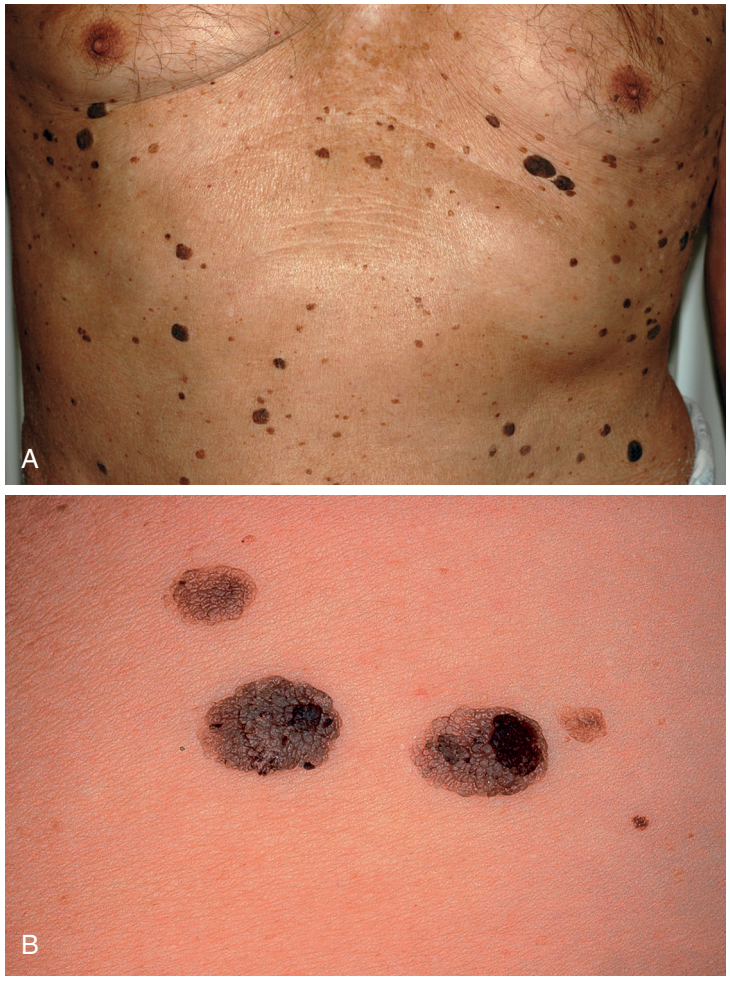

FIGURE 407-8. Seborrheic keratoses. A, Multiple seborrheic keratoses of the anterior trunk vary in size and color. **B,** Sharply demarcated, pigmented papules and plaques with a papillomatous surface and horn pseudocysts. Note the "stuck-on" appearance. (From Bolognia. *Dermatology*, 4th ed.)

papules on the gums and tongue; fibrous papules; and multiple hamartomas involving the breast, thyroid, intestines, ovary, and cerebellum.

ADNEXAL TUMORS

Adnexal tumors arise from hair follicles or glands and are commonly found on the face or scalp. Trichoepitheliomas resemble basal cell carcinomas. Sebaceous hyperplasia consists of small yellow papules with a central depression. Adnexal tumors of sebaceous origin, including sebaceous adenomas and sebaceous carcinomas, can also occur on the face, where they may be markers of the Muir-Torre syndrome of familial breast and colon cancer. Epidermal or sebaceous cysts, which are found in acne or as single firm nodules with a central pore, are filled with sebum or keratin. Epidermoid tumors of the scalp and a family history of colon cancer raise questions of a diagnosis of Gardner syndrome (Chapter 179).

DERMATOFIBROMAS AND COLLAGENOMAS

Fibroblasts, the resident cells of the dermis, produce collagen, elastin, and mucopolysaccharides. Accumulation of these products results in sclerosis, papules, or nodules. Fibroblasts in small, dense clusters form firm brown or tan papules known as dermatofibromas. Dermatofibromas are hypertrophic scars that are commonly found on the extremities and that may form after insect bites or trauma. They are firm and well-demarcated papules, and the skin dimples when lateral pressure is applied. Dermatofibromas can be treated, but increased scarring may occur. The malignant counterpart is dermatofibroma sarcoma protuberans, which is a poorly defined, rapidly expanding, dermal, malignant tumor. Overlying erythema or hyperpigmentation is often present.

Some individuals have more pronounced and hypertrophic scar formation known as keloids, with an autosomal dominant or autosomal recessive inheritance pattern. Keloids, which are shiny and firm in appearance, result from an overproduction of collagen. They are especially common on the anterior chest, neck, and earlobes. Treatment is discussed in Chapter 408.

Collagenomas and elastic tumors appear as small white to yellow papules and are found in the skin and bone of patients with Buschke-Ollendorff syndrome. *Pseudoxanthoma elasticum* (Chapter 239), an autosomal recessive disorder, typically manifests as cutaneous yellow plaques on the neck or antecubital fossa from damaged elastin tissue. Mucin cysts are gray, shiny, well-demarcated, round nodules that generally arise on the mucosa or on the digits, where they may have an underlying connection to the joint space.

NEURAL CREST CELL TUMORS

Benign tumors in the dermis arising from neural crest cells include neurofibromas (soft, flesh-colored papules; Fig. 407-11), schwannomas (larger subcutaneous soft tumors or plaques; Fig. 407-12), and melanocytic lesions. Although solitary neurofibromas may occur, multiple lesions with café-au-lait spots (tan macules) or axillary freckling (Crowe sign) are diagnostic of neurofibromatosis type I, an autosomal dominant disorder caused by mutations in neurofibromin (Chapter 385).[14] Schwannomas can become malignant and manifest as dermal nodules.

Merkel cell carcinoma, which is a neuroendocrine carcinoma of the skin, is a particularly aggressive small cell tumor arising from the cutaneous nerve endings or Meissner corpuscles. Merkel cell polyomavirus (Chapter 341) is associated with development of Merkel cell carcinoma. Merkel cell carcinoma may present as a solitary flesh-colored to purple dome-shaped papule on the head or neck (Fig. 407-13). Sentinel lymph node biopsy is recommended in all patients with primary Merkel cell carcinoma. Treatment requires full excision, radiation therapy, and often chemotherapy because the cancer tends to recur and metastasize. PD-1 axis checkpoint inhibitors, such as pembrolizumab (2 mg/kg every 3 weeks), avelumab (10 mg/kg every 2 weeks), and nivolumab (240 mg every 2 weeks), provide an objective response rate between about 55 to 70% in chemotherapy-naïve advanced Merkel cell carcinoma.[15]

MELANOCYTIC LESIONS

Benign melanocytic moles or nevi (new) are discrete nests of melanocytes acquired during childhood and young adulthood, stimulated by sun exposure. Nevi are benign and composed of melanocytes (Chapter 188). They regress with age and change in color during pregnancy. Benign melanocytic nevi are formed by nests of melanocytes at the epidermal junction (junctional nevi), in the dermis (intradermal nevi), or in both compartments (compound nevi). Their appearance depends on type and age of the lesion. Junctional nevi (Fig. 407-14) are small, flat, and light to dark brown. Intradermal nevi are soft, flesh-colored to pink papules with smooth regular borders and surface. Compound nevi are globular papules with brown pigmentation. Blue nevi (Fig. 407-15) are flat, grayish blue, and regular. Small congenital nevi are dark brown, dysplastic nevi (Fig. 407-16), have variegated colors, and may give rise to melanoma. More than 10 large, atypical moles with irregular borders and colors confer higher risk of developing melanoma, especially with a positive family history. Other recognized risk factors for melanoma include having more than 50

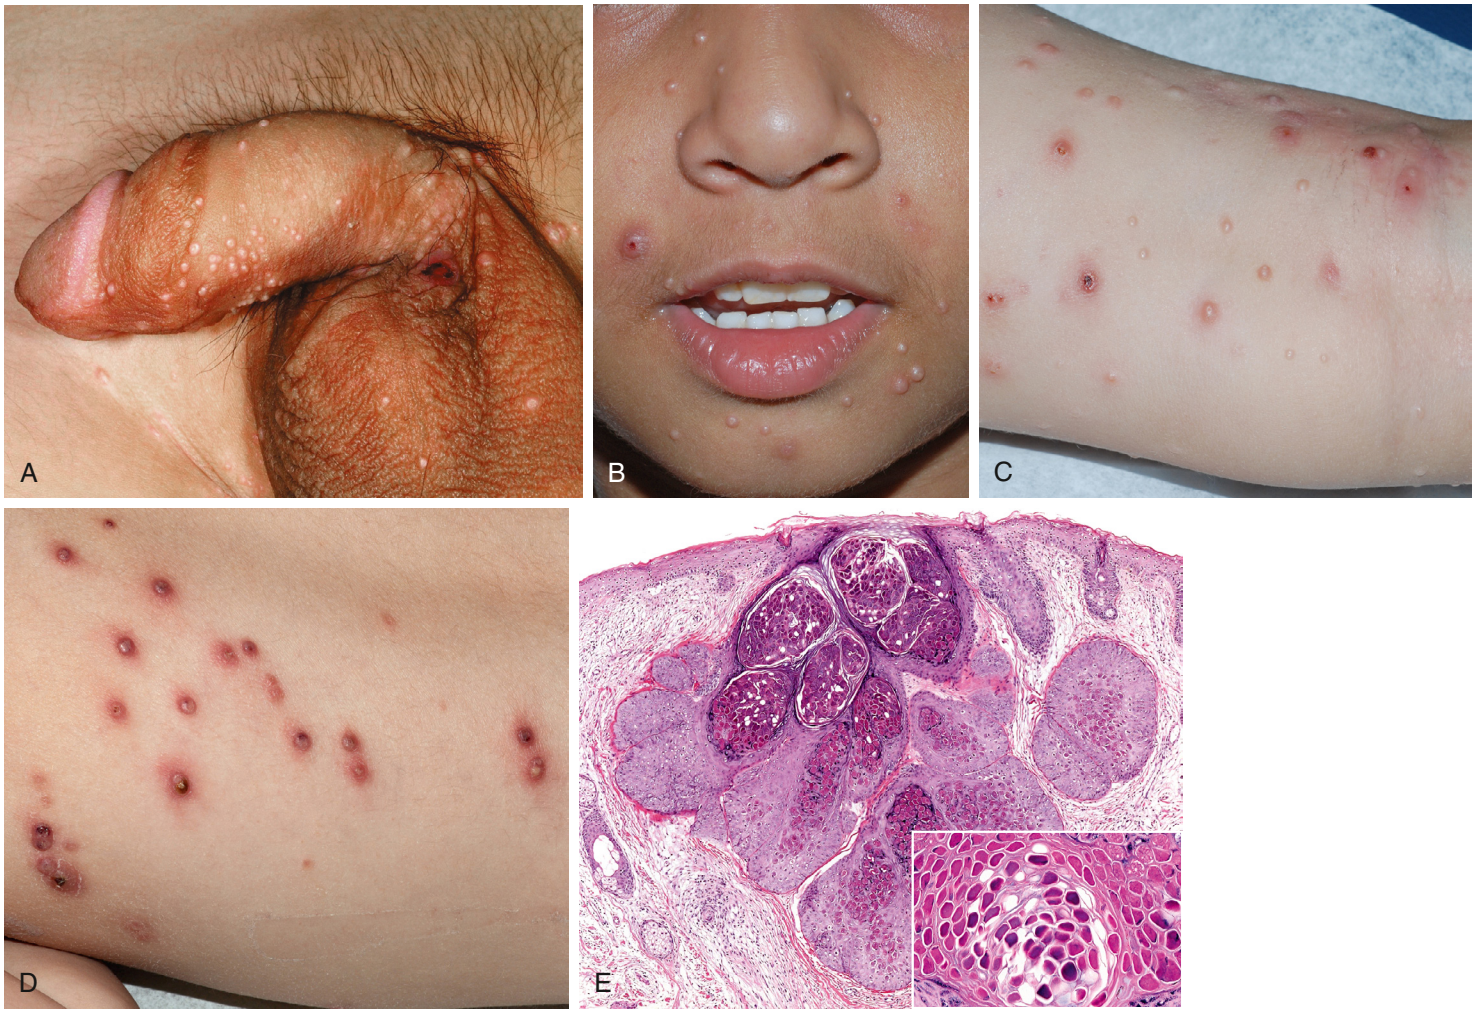

FIGURE 407-9. Molluscum contagiosum. Multiple pearly, umbilicated papules in the genital area (**A**) and on the face (**B**); note the inflamed lesion on the right cheek. Inflammatory reactions are a sign of the host immune response to the virus. **C**, Inflamed lesions surrounded by "molluscum dermatitis." **D**, Pustular presentation of an inflamed molluscum; culture revealed only normal skin flora. **E**, Histologic evaluation shows numerous molluscum bodies (*inset*). Demonstrating these bodies in a saline preparation of expressed lesional contents serves as a technique for making a bedside diagnosis. (B–D, Courtesy Julie V. Schaffer, MD. E, Courtesy Lorenzo Cerroni, MD.)

FIGURE 407-10. Cowden syndrome: cobblestone gums (*left*) and tricholemmoma (*right*).

small nevi, red or blonde hair, or fair skin that burns and a history of blistering sunburns as a child. Patients with higher risk for melanoma should have surveillance and regular skin examinations.[16]

LANGERHANS CELL HISTIOCYTOSIS

Skin surveillance is mediated by antigen-presenting cells: Langerhans cells, dermal dendritic cells, and skin-homing T lymphocytes.[17] Proliferation of Langerhans cells is called histiocytosis (Chapter 155). Childhood histiocytosis X is manifested as severe seborrheic dermatitis of the scalp and gluteal areas with underlying purpura and may result in the hemophagocytic syndrome. In adults, lesions appear in the intertriginous areas (Fig. 407-17). Patients with the non–Langerhans cell histiocytosis have lytic bone involvement (eosinophilic granulomas) or diabetes insipidus (Hand-Schüller-Christian syndrome).

VASCULAR LESIONS

HEMANGIOMAS

Benign capillary, or cherry, hemangiomas are bright cherry-red to purple papules, generally less than 5 mm in diameter. They appear on the trunk with

FIGURE 407-11. Multiple cutaneous neurofibromas. Soft, skin-colored to pinkish-tan, dome-shaped or polypoid, well-demarcated papules and nodules of various sizes (**A–C**) can occur in patients with neurofibromatosis. Neurofibromas may be superimposed on café-au-lait macules and lentigines (**B, C**). (A, B, Courtesy Julie V. Schaffer, MD.)

FIGURE 407-12. Solitary schwannoma. Skin-colored nodule on the plantar surface of the great toe. (Courtesy Julie V. Schaffer, MD.)

FIGURE 407-13. Merkel cell carcinoma (primary neuroendocrine carcinoma). A, A rapidly growing, violaceous nodule on the toe. **B**, Large, eroded, erythematous nodule arising within sun-damaged skin of the cheek. (B, Courtesy Lorenzo Cerroni, MD.)

FIGURE 407-14. Junctional nevus. (From Bolognia. *Dermatology*, 4th ed.)

FIGURE 407-15. Benign blue nevus. Well-circumscribed, dark blue, flat papule. (From Bolognia. *Dermatology*, 4th ed.)

FIGURE 407-16. Atypical melanocytic nevi. A, There is asymmetry as well as several shades of brown, simulating the clinical features seen in cutaneous melanoma. **B,** In addition to multiple atypical nevi, patients can have numerous typical nevi. (From Bolognia. *Dermatology*, 4th ed.)

aging and may be numerous (Fig. 407-18). Pyogenic granulomas can resemble hemangiomas but contain polymorphonuclear leukocytes, are friable, and bleed easily. Multiple pyogenic granulomas are seen in infectious bacillary angiomatosis (due to *Bartonella henselae* or *Bartonella quintana*) in immunocompromised hosts (Chapter 291). Cavernous or strawberry hemangiomas can also appear in the neonatal period as rapidly growing vascular tumors; they may obstruct the eye or the pharynx before regressing.

TREATMENT AND PROGNOSIS

Propranolol 2 to 3 mg/kg/day in two or three divided doses for 6 months may decrease the hemangioma's volume, color, and elevation in children younger than 5 years of age.[18] Corticosteroids, interferon, or antiangiogenic factors also can treat these lesions if propranolol is not successful. Cavernous hemangiomas are deeper and less likely to resolve than smaller lesions. When associated with platelet consumption and a risk for severe bleeding, the Kasabach-Merritt syndrome is present.

SARCOMAS

Kaposi sarcoma (Chapter 359) is a disseminated angiomatosis that arises from viral IL-8 production by herpesvirus 8. Lesions are symmetrical purple, red, gray, or brown patches, papules, nodules, or ulcers (Fig. 407-19). Mucosal involvement is more common in advanced disease. Kaposi sarcoma in young African adults and Kaposi sarcoma associated with human immunodeficiency virus (HIV) infection often have a more aggressive course than Kaposi sarcoma in elderly men of Mediterranean background, whose disease is indolent and often confined to the lower extremities. Treatment of HIV disease with highly active antiretroviral therapy has been associated with a marked decreased

FIGURE 407-17. Histiocytosis X in intertriginous areas.

incidence and severity of HIV-associated Kaposi sarcoma.[19] Treatment is described in Chapter 359.

Angiosarcomas are malignant purple to red vascular tumor nodules that are more common in elderly individuals or on the extremities of patients with chronic lymphedema. To help distinguish cutaneous angiosarcomas

FIGURE 407-18. Benign capillary hemangioma.

FIGURE 407-19. Kaposi sarcoma in a patient with AIDS. Violet-red papules or nodules are often oval to lanceolate and are usually more widely distributed than in classic Kaposi sarcoma. (From Bolognia. *Dermatology*, 4th ed.)

from benign histologic mimics, immunohistochemistry staining for the ERG protein, which is a member of the erythroblast transformation-specific family of transcription factors, is a specific and sensitive marker for endothelial differentiation. Treatment is described in Chapter 187.

INFLAMMATORY AND HEMATOPOIETIC PAPULES AND TUMORS

Inflammatory diseases of the skin involve the superficial or dermal vessels or subcutaneous tissue. Inflammatory infiltrates can be mixed or restricted in nature. Lymphocytes, polymorphonuclear leukocytes, histiocytes, eosinophils, and plasma cells are involved in the most common inflammatory reactions. Hematologic malignancies can present with secondary skin lesions, including patches, nodules, papules, or vasculitic lesions. Skin-homing $CD4^+$ T cells give rise to cutaneous T-cell lymphomas. Mycosis fungoides (Chapter 171) lesions are pleomorphic pink, white, or brown patches or plaques; alopecia; or diffuse erythroderma with blood involvement (Sézary syndrome). Early patch or plaque mycosis fungoides is indistinguishable from chronic eczematous or psoriasiform dermatitis. Tumors occur late in mycosis fungoides and

FIGURE 407-20. Cutaneous mucosa-associated lymphoid tissue (MALT) lymphoma.

can transform to a large cell lymphoma phenotype, with or without expression of CD30. Peripheral cutaneous T-cell lymphomas also may be found in subcutaneous tissue as panniculitic lesions. Lymphomatoid papulosis is characterized by crops of red to pink self-regressing papules with histologic findings similar to those of anaplastic large cell lymphoma (Chapter 171), including expression of CD30 antigen. Clinically, lymphomatoid papulosis presents as self-regressing papules, $CD3^+$ anaplastic T-cell lymphomas can present as tumors, and patients with transformed $CD30^+$ mycosis fungoides initially have patch or plaque stage disease before developing tumors. Treatment of lymphomatoid papulosis consists of topical corticosteroids, methotrexate, or bexarotene. For $CD30^+$ anaplastic T-cell lymphoma, therapeutic options include radiation therapy, methotrexate, bexarotene, brentuximab vedotin, and chemotherapy (Chapter 171). Natural killer T-cell lymphomas, immunoblastic lymphomas, and plasmacytoid dendritic cell tumors appear as brown to purple dermal nodules, often with purpura.

Cutaneous B-cell lymphomas present as pink, infiltrated, dome-shaped, shiny papules or tumors. Whereas follicular B-cell lymphoma is commonly located on the face, scalp, or upper part of the back, mucosa-associated B-cell tumors are more common on the trunk. With the exception of large B-cell lymphoma, follicular and mucosa-associated lymphoid tissue (MALT) B-cell lymphomas of the skin are indolent. Cutaneous MALT lymphomas (Fig. 407-20) have been associated with *Borrelia* spp infection (Chapter 296), *Helicobacter pylori* infection, and chronic inflammation. Plasmacytomas can arise in the skin, in bone, with multiple myeloma (Chapter 173), or independently. Extramedullary hematopoiesis or endometriosis can be associated with red or brown nodules in the dermis.

GRANULOMATOUS DISEASES

Sarcoidosis is an inflammatory granulomatous process manifested as ichthyosis, papules, plaques, or tumors with an apple-jelly color (Fig. 407-21). Patients with lepromatous leprosy also can have histiocytic plaques or tumors (Fig. 407-22); treatment of leprosy may induce an inflammatory reaction called erythema nodosum leprosum. Granulomatous mycosis fungoides, which is a variant of cutaneous T-cell lymphoma, is difficult to diagnose and treat. Granulomatous inflammation within the dermis can result in damage to collagen, as seen in granuloma annulare (ringlike pink to red infiltrated lesions, often on the hands or elbows), rheumatoid nodules that occur on the extensor surface of the arms, and necrobiosis lipoidica on the shins of patients with diabetes. All three lesions typically include fibrin deposits within dermal blood vessels. Multicentric reticulohistiocytosis is a rare paraneoplastic syndrome in which histiocytic nodules form over joints with associated arthritis.

INFLAMMATORY SKIN LESIONS AND NODULES

Inflammatory skin nodules arise from inflamed blood vessels (vasculitis) or adipose tissue (panniculitis). Either can arise in response to underlying infection or antigen stimulation with influx of inflammatory cells. Vasculitis is categorized by vessel size and circulating immune complexes. Damage to blood vessels results in leakage of red blood cells with the development of purpura (nonblanching red to purple lesions; Chapter 249).

Sweet syndrome, also called febrile neutrophilic dermatosis (Fig. 407-23), is accompanied by fever, leukocytosis, and tender reddish skin plaques.[20] Some

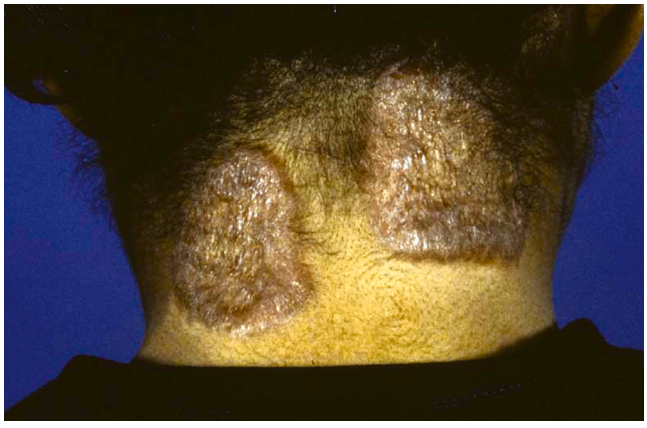

FIGURE 407-21. Cutaneous sarcoidosis.

FIGURE 407-22. Lepromatous leprosy. A, Numerous erythematous papules and nodules on the forearms and hands. **B,** Infiltrated nodules coalescing on the forehead with leonine facies and madarosis. Note the ocular involvement.

FIGURE 407-23. Sweet syndrome. A, Scattered tender, edematous pink papules, pustules, and plaques on the chest. **B,** The edema can be quite marked as seen in these lesions on the upper back. (B, Courtesy Kalman Watsky, MD.)

patients also have arthralgia. Biopsy shows sheets of leukocytes filling the upper dermis in the absence of infection. It can be idiopathic; drug induced; or associated with an underlying disease, typically with an underlying streptococcal infection, acute myelogenous leukemia, other malignancies, inflammatory bowel disease, or rheumatoid arthritis. Use of hematopoietic growth factors also can precipitate Sweet syndrome. Sweet syndrome, but not erythema elevatum diutinum, is highly responsive to corticosteroids (oral prednisone 1 to 2 mg/kg/day gradually tapered over 6 weeks to 3 months) or indomethacin (150 mg per day for 1 week; then 100 mg per day for 2 weeks), but oral dapsone (100 to 200 mg/day) can improve both conditions.

Pyoderma gangrenosum is a trauma-induced ulcer that is part of the spectrum of Sweet syndrome. Diagnosis requires skin biopsy, cultures, and serologic testing for other associated diseases. Treatment with prednisolone (0.75 mg/kg/day, maximum 75 mg/day) or cyclosporine (4 mg/kg/day, maximum 400mg/day) is equally effective.[A10] Decubitus ulcers require débridement, elimination of local pressure, and attention to nutrition.

Erythema elevatum diutinum is manifested as multiple, infiltrated pink, yellow, red, or violaceous nodules or papules that may be painful or asymptomatic. The lesions can coalesce to form gyrate lesions on the dorsum of the hands or extensor surfaces similar to granuloma annulare. Erythema elevatum diutinum is associated with upper respiratory infections (especially *Streptococcus* spp), HIV infection, and inflammatory bowel disease. Clinically, the lesions look similar to Sweet syndrome, but their underlying histopathology (a necrotizing vasculitis with neutrophils and hyalinization of the vessels) can be distinguished from the neutrophils seen in the upper dermis in Sweet syndrome on biopsy.

POLYARTERITIS NODOSA AND PANNICULITIS

Polyarteritis nodosa (Chapter 249) arises in larger arterioles and may be associated with hepatitis C infection, mesenteric aneurysms, cryoglobulinemia, cutaneous ulceration, and livedo reticularis. Polyarteritis nodosa is distinct from small vessel leukocytoclastic vasculitis, which is characterized by smaller areas (a few millimeters) of purpura.

In the clinical setting, *panniculitis* occurs more frequently than nodular vasculitis. The diagnosis of vasculitis versus septal or lobular panniculitis requires an excisional biopsy, including fat, with appropriate cultures and stains.

Erythema nodosum (Fig. 407-24) is a septal panniculitis characterized by tender nodules that are 1 to 2 cm in diameter with warm, pink, overlying epidermis. They appear in crops on the extremities. A perivascular inflammatory infiltrate is present around small intralobular vessels without vasculitis. Erythema nodosum arises frequently in response to sarcoidosis (Chapter 83), various infections, inflammatory bowel disease, or drug use and less commonly in patients with azathioprine-induced pancreatitis or primary biliary cirrhosis. Often, however, the underlying cause remains unknown (Table 407-6).[21]

Lobular panniculitis with necrosis and purpura is called nodular vasculitis or erythema induratum. Nodular vasculitis is characterized by painful, chronic, recurrent nodules on the shin or thigh that become bluish, ulcerate, and heal with scarring. Erythema induratum (Fig. 407-25) is exacerbated by cold exposure and is sometimes associated with *Mycobacterium tuberculosis* (Chapter 299).

True lobular panniculitis, with or without fat necrosis, is more frequent in men with underlying pancreatitis (Chapter 130) and may precede pancreatic cancer (Chapter 180). The lesions have a predilection for the anterior aspect of the shins and may be fluctuant as a result of fat necrosis. *Lupus panniculitis*, or lupus profundus, which involves the fat, is diagnosed by overlying granular immune complex deposition of IgM along the dermal-epidermal junction and is often difficult to distinguish from subcutaneous panniculitic T-cell lymphoma. Subcutaneous panniculitic γ/δ T-cell lymphoma is more aggressive and has a poor prognosis compared with α/β panniculitic T-cell lymphoma. Lupus panniculitis of the breast, which can be mistaken for adenocarcinoma, is treated with antimalarials or corticosteroids. Lobular panniculitis with calcification of the small arterioles, which occurs in the setting of renal failure with hyperparathyroidism, is called calciphylaxis (Chapter 116). Granulomatous lobular panniculitis may also arise in the setting of schistosomiasis (Chapter 326), Sjögren syndrome (Chapter 247), Crohn disease (Chapter 127), sarcoidosis (Chapter 83), ruptured epidermal cysts, atypical mycobacterial infection (Chapter 300), or tuberculosis (Chapter 299).

FUNGAL INFECTIONS

In immunocompromised patients, necrotic or granulomatous lobular panniculitis can be caused by disseminated fungal infections with *Candida* spp, *Sporothrix schenckii, Cryptococcus* spp, *Histoplasma* spp, *Nocardia* spp, *Rhizopus* spp, *Aspergillus* spp, *Fusarium* spp, or chromomycosis. Fungal mycelia invade vessel walls, where they produce purpuric and painful lesions that may ulcerate. Osler nodes, which are tender nodular vasculitic lesions on the extremities, occur in the setting of bacterial endocarditis (Chapter 61). Staphylococcal or streptococcal sepsis may be manifested as pustules, papules, or panniculitic lesions.

ATROPHIC AND SCLEROTIC LESIONS

ATROPHIC LESIONS

Atrophic lesions result from thinning or loss of the epidermal and dermal layers (Table 407-7).[22] Examples are photoaging caused by loss of epidermal thickness and collagen, discoid lupus, and genetic disorders of collagen production (e.g., Ehlers-Danlos syndrome; Fig. 407-26). Epidermal wrinkling can result in a cigarette paper appearance with prominence of the underlying blood vessels. High-potency topical corticosteroids cause loss of collagen, resulting in atrophy. In Cushing syndrome (Chapter 208), striae appear as red or purple streaks because the underlying dermis can be seen through the epidermis.

Aging skin is most pronounced in sun-exposed areas, but intrinsic aging beginning as early as 30 years of age is characterized by abnormalities in the formation of elastin fibers. Aging of the skin is accompanied by decreased rete ridges and diminished circulation. Sunlight ages the skin by inducing proteolytic enzymes that digest the underlying collagen and elastin (wrinkles). In addition, sun exposure induces pigment incontinence (freckling), increased junctional nevi, and proliferation of benign keratinocyte growths (seborrheic keratoses).

Atrophy can also result from ongoing inflammatory processes that cause scarring, such as collagen vascular disease or mycosis fungoides. The cutaneous and discoid forms of lupus erythematosus (Chapter 245) are manifested as scaly plaques with atrophy or alopecia on sun-exposed areas; the systemic form is characterized by malar rash, urticaria, or vasculitic lesions. Dermatomyositis (Chapter 248) can be associated with collagen vascular disease or malignancy; periorbital suffusion, telangiectasia of the nail beds, and Gottron papules or

TABLE 407-7 ATROPHIC SKIN CONDITIONS WITH SCARRING, ULCERATIONS, OR TELANGIECTASES

ATROPHY
Epidermal: chronic corticosteroid use, photoaging, mycosis fungoides
Dermal elastin: anetoderma, cutis laxa, intrinsic aging
Dermal collagen: Ehlers-Danlos syndrome, aging
Subcutaneous: granulomatous slack skin (a mycosis fungoides variant)
Lipodystrophy (loss of fat)
SCARRING OR ATROPHY WITH TELANGIECTASIAS
Discoid and subacute cutaneous lupus erythematosus
Dermatomyositis
Keloid formation
Large plaque parapsoriasis (poikiloderma vasculare atrophicans variant of mycosis fungoides)
Photoaging
Necrobiosis lipoidica diabeticorum
Radiation dermatitis
Porphyrias
Thermal burns (erythema ab igne)
SCLEROSIS OR INFILTRATIVE PROCESSES
Amyloidosis
Systemic sclerosis, scleroderma
Localized sclerosis, morphea
Lichen sclerosis et atrophicus
Lichen myxedematosus or papular mucinosis (mucopolysaccharide deposition with paraproteinemia)
Myxedema (mucin deposits with anti–thyroid-stimulating hormone receptor antibodies)
ULCERATIONS
Secondary breakdown of any blister or nodule: infectious, inflammatory, tumor, vasculitis
Decubitus or pressure ulcers
Genital ulcers: syphilis, herpes simplex, chancroid, lymphogranuloma venereum, Behçet syndrome
Pyoderma gangrenosum, Sweet syndrome

FIGURE 407-26. Atrophic skin in Ehlers-Danlos syndrome type 2.

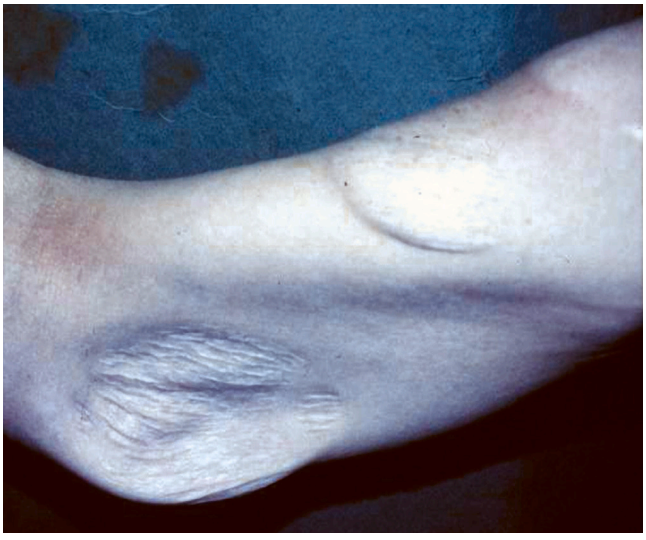

FIGURE 407-27. Anetoderma.

FIGURE 407-28. Lichen myxedematosus.

FIGURE 407-29. Nephrogenic systemic fibrosis.

scaly lesions over the joints are the skin manifestations. Anetodermas are localized sclerotic lesions (Fig. 407-27) with distinctive clinical features from underlying inflammation.

Eosinophilic fasciitis is accompanied by nodules or sclerosis of the lower extremities, myopathy, pulmonary disease, and eosinophilia. This syndrome, which follows the ingestion of L-tryptophan or its contaminants, resembles the panniculitis seen in systemic sclerosis, in which fat lobules are replaced by new collagen formation. Eosinophilic cellulitis, or Wells syndrome, is manifested as nodules, papules, or ulcerative lesions, as well as red plaques in which eosinophils infiltrate the area between collagen fibers.

SCLEROTIC LESIONS

Sclerotic lesions are accompanied by more collagen production, which results in skin with a glossy appearance. Sclerosis may also result from the accumulation of mucopolysaccharides in scleromyxedema (lichen myxedematosus) or from amyloid deposits. Papular mucinosis, lichen myxedematosus (Fig. 407-28), and scleromyxedema are a spectrum of diseases that are caused by deposition of hyaluronic acid. An entity associated with renal failure and gadolinium exposure, nephrogenic fibrosing dermopathy (Chapter 246; Fig. 407-29),

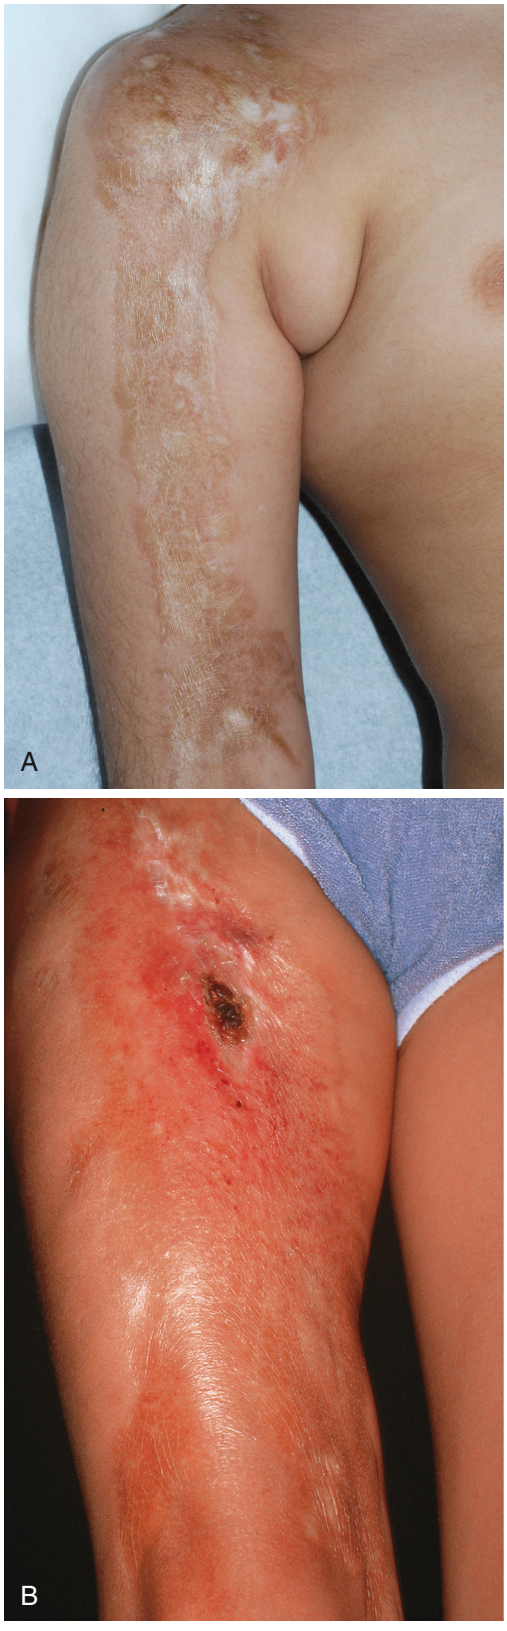

FIGURE 407-30. Linear morphea of an extremity. A, Linear sclerotic band of the arm with both hyperpigmentation and hypopigmentation. The majority of patients with linear morphea have unilateral involvement. **B,** More inflammatory phase with ulceration in addition to induration. (A, Courtesy Julie V. Schaffer, MD.)

is also characterized by acral fibrosis and deposition of hyaluronate in the skin. In scleroderma (Chapter 246), increased collagen deposition may be associated with Raynaud syndrome, calcinosis, and telangiectasia. A localized form of scleroderma, termed *morphea*, may occur down the center of the face (coup de sabre) or as plaques on the extremities (Fig. 407-30), after radiation exposure, or with *Borrelia* spp infection. Lichen sclerosis et atrophicus is a superficial inflammatory morphea characterized by white atrophic patches, especially in the genital region. Widespread systemic sclerosis may also follow bone marrow transplantation in the setting of chronic graft-versus-host disease.

TELANGIECTASIA

Telangiectasia is prominence of skin blood vessels that frequently accompanies atrophic as well as sclerotic processes and is common in photoaged skin and after radiation therapy. Telangiectasia of the mucous membranes is found in Osler-Weber-Rendu syndrome (Chapter 159), and vascular spiders are found both in α_1-antitrypsin deficiency and alcoholic liver disease. The presence of telangiectasia, hyperpigmentation, and hypopigmentation (poikiloderma) in sun-shielded areas of the body should alert the clinician to the diagnosis of early mycosis fungoides.

ULCERS

Ulcers are secondary skin lesions that may arise from trauma, loss of proper blood supply, aging, vasculitis, blister formation, infection, or underlying neoplasia. Ulcers may be shallow erosions (loss of the epidermis) or may be deeper and involve the dermis and underlying subcutaneous structures. Ulcers most commonly appear on the lower extremities, where they result from stasis dermatitis and venous insufficiency, arteriolar insufficiency, diabetic neuropathy, or vasculitis.

Venous stress ulcers are described Chapter 68, diabetic ulcers in Chapter 210, decubitus ulcers in Chapter 24, and genital ulcers in Chapter 264 (see Table 264-3).

408 INFECTIONS, PIGMENTATION DISORDERS, REGIONAL DERMATOLOGY, AND DISTINCTIVE LESIONS IN BLACK SKIN

JEAN BOLOGNIA AND AMY MCMICHAEL

INFECTIONS, INCLUDING CELLULITIS

Cutaneous infections can be divided into four major categories: bacterial, fungal (Chapter 405), viral, and parasitic (Table 408-1).

ABSTRACT

This chapter covers five major areas within dermatology: (1) cutaneous infections, including those that are bacterial, viral, fungal, and parasitic; (2) hypopigmentation; (3) hyperpigmentation; (4) distinctive lesions in Black skin; and (5) regional dermatoses. The disorders of hypopigmentation are divided into diffuse, circumscribed, linear, and guttate, whereas the disorders of hyperpigmentation are divided into diffuse, circumscribed, linear, and reticulated. Examples of disorders that are observed more commonly in Black skin include central centrifugal cicatricial alopecia, acne keloidalis nuchae, and pseudofolliculitis barbae. Distribution patterns are very helpful when generating differential diagnoses for skin diseases, and schematics of distribution patterns of several common disorders are provided, including those of psoriasis, atopic dermatitis, seborrheic dermatitis, acne, and vitiligo.

KEYWORDS

regional dermatoses

TABLE 408-1 SKIN INFECTIONS

BACTERIAL DISEASES
Impetigo
Ecthyma
Folliculitis
Furuncle/carbuncle
Abscess
Erysipelas
Cellulitis
Necrotizing fasciitis
Ecthyma gangrenosum
Other
Gram-negative cocci: meningococcemia, gonococcemia
Gram-positive bacilli: erythrasma, anaerobic cellulitis
Spirochetes: Lyme disease, syphilis, endemic treponematoses
Mycobacterial infections
Rickettsial infections
VIRAL DISEASES
Herpes simplex virus: oral, genital, digital (whitlow)
Human papillomavirus: common warts, condyloma acuminata
Poxvirus: molluscum contagiosum, monkeypox (MPOX)
Varicella-zoster virus
Viral exanthems (e.g., enteroviruses, rubeola, rubella, parvovirus, Epstein-Barr virus, adenovirus, dengue virus, Zika virus, chikungunya virus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), human immunodeficiency virus [seroconversion])
FUNGAL DISEASES
Candidiasis
Tinea (dermatophytoses): pedis, corporis, cruris, manuum, capitis
Pityriasis (tinea) versicolor
Emboli (e.g., *Aspergillus, Mucor* spp)

BACTERIAL INFECTIONS

Of the cutaneous bacterial infections, impetigo, folliculitis, furuncles, and cellulitis are most commonly encountered.

IMPETIGO

Impetigo, which is caused by *Staphylococcus aureus* or group A β-hemolytic streptococci, is usually seen as honey-colored crusts (Fig. 408-1); less often, subcorneal (superficial) bullae are present. This infection is most commonly found on the face in children, but it can develop at any site where the cutaneous barrier has been disrupted (e.g., areas of dermatitis, sites of trauma, or arthropod bites). A deeper, but less common, bacterial infection of the skin is ecthyma, which is most frequently streptococcal in origin; it is characterized by thick hemorrhagic crusts overlying erosions or ulcerations, usually 0.5 to 1.5 cm in diameter. These lesions favor the extremities, especially in the setting of lymphedema. Ecthyma should not be confused with ecthyma gangrenosum, which represents an embolic phenomenon most often caused by bacteremia with gram-negative bacilli.

TREATMENT

Although mild cases of impetigo usually respond to topical 2% mupirocin three times daily, 1% retapamulin twice daily, or ozenoxacin 1% twice daily,[A1] more severe impetigo and ecthyma require oral antibiotics that cover *S. aureus* (e.g., dicloxacillin, 250 mg orally [PO] four times daily, or cephalexin, 250 mg PO four times daily). Compared with furuncles and abscesses, impetigo is less often due to methicillin-resistant *S. aureus* (MRSA).

FIGURE 408-1. Impetigo in an infant and marked involvement of the face with honey-colored crusts and superficial erosions. (Courtesy Yale Dermatology Residents' Slide Collection.)

FOLLICULITIS

The initial lesions of folliculitis are follicular pustules that are often surrounded by a rim of erythema (Chapter 406). Culture of pustular contents yields normal flora more often than *S. aureus* or gram-negative bacilli. *Pseudomonas* folliculitis, which favors the trunk, is usually associated with the use of hot tubs or whirlpools because their higher temperatures (vs. swimming pools) make eradication of *Pseudomonas* more difficult (see Fig. 406-27 in Chapter 406).

FURUNCLES

Furuncles, also called *boils*, represent *S. aureus* cutaneous infections that are localized primarily within the dermis. In contrast to folliculitis, the lesions are larger and manifest as tender erythematous nodules (Fig. 408-2). A central follicular structure may be noted, as may a central pustule ("pointing").

TREATMENT

Because a furuncle is an abscess, the preferred treatment is incision and drainage followed by oral antistaphylococcal antibiotics (e.g., dicloxacillin, 250 mg PO four times daily, or cephalexin, 250 mg PO four times daily); if MRSA is likely (e.g., use of health care facilities such as dialysis units, participation in skin-to-skin contact sports, an elevated prevalence of methicillin-resistant isolates in the local community), the antibiotic should be changed to doxycycline (100 mg PO twice daily), minocycline (100 mg PO twice daily), clindamycin (300 to 600 mg PO three times daily), trimethoprim-sulfamethoxazole (160 mg/800 mg PO twice daily), linezolid (600 mg PO twice daily), or omadacycline (450 mg PO on day 1 then 300 mg once daily),[A2] depending on local sensitivity patterns.[1] The duration of therapy is usually 10 to 14 days. Carbuncles, which are larger, more complex, and more extensive versions of furuncles, may be accompanied by systemic symptoms such as fever. In addition to incision and drainage, they may require a more prolonged course of antibiotic therapy.

CELLULITIS

Cellulitis is a fairly common cutaneous infection that occurs most often on the lower extremities. Locally, it manifests as erythema, edema, warmth, and tenderness; systemic findings can include fever, malaise, and leukocytosis. Most cases are bacterial in origin, but some are caused by fungal infections (e.g., *Cryptococcus* spp) or chemical reactions (e.g., extravasated oxacillin or calcium salts). Bacterial cellulitis is most commonly caused by group A β-hemolytic streptococci and *S. aureus*, with the former being associated with the more severe, necrotizing variant. Interestingly, the skin microbiome in the vicinity of the infection tends to be very similar to the contralateral microbiome, but both microbiomes typically differ from those of control patients. In patients who have diabetes or are immunocompromised, cellulitis can be caused by gram-negative bacilli or atypical

FIGURE 408-2. Furuncle with surrounding cellulitis. This common presentation of methicillin-resistant *Staphylococcus aureus* should be treated with incision and drainage as well as the administration of systemic antibiotics. (Courtesy Yale Dermatology Residents' Slide Collection.)

FIGURE 408-3. Bullous and hemorrhagic cellulitis of the shin. (Courtesy University of Southern California Dermatology Residents' Slide Collection.)

mycobacteria. Risk factors include a preceding break in the skin barrier, edema secondary to venous hypertension, lymphedema, and previous bouts of cellulitis.

Although the diagnosis of cellulitis is usually fairly straightforward (Fig. 408-3), it can sometimes be difficult and aided by dermatologic consultation in patients with chronic lower extremity edema, especially in patients who are afebrile and have persistent discoloration.[A3] One complication of chronic lower extremity edema is lipodermatosclerosis (i.e., inflammation followed by fibrosis of subcutaneous fat), which is seen acutely as erythema, warmth, and tenderness and is easily confused with cellulitis. The skin above the medial malleolus is often the initial site of involvement for lipodermatosclerosis, but the inflammation can extend onto the shin and calf. The chronic phase of lipodermatosclerosis is characterized by induration, a permanent brown-red to violet discoloration of the skin, and an "inverted wine bottle" appearance of the distal end of the lower extremity. It is important for the clinician to realize that in patients with chronic lipodermatosclerosis and superimposed cellulitis, the skin will never return to the color of uninvolved skin, even after adequate antibiotic therapy.

Unless there is an associated bacteremia, the diagnosis of cellulitis is primarily clinical. It also can be misdiagnosed when an abscess or a noninfectious condition, such as stasis dermatitis, is the cause.[2] In immunocompromised hosts, a saline injection followed by aspiration and culture can be helpful. Histologically, cellulitis is characterized by an infiltrate of neutrophils within the dermis. Skin biopsy can exclude disorders that may be confused with cellulitis, such as contact dermatitis, erythema migrans, inflammatory carcinoma, toxic erythema of chemotherapy, and Wells syndrome (an idiopathic disorder in which eosinophils infiltrate the dermis).

TREATMENT

Cellulitis resides in the middle of a spectrum of soft tissue infections that includes erysipelas (more superficial and more sharply demarcated; Fig. 408-4) at one end and necrotizing fasciitis (deeper, more necrotic, and undermining) at the other. In healthy adults, erysipelas can be treated with oral penicillin (200,000 units four times daily) or, if methicillin-sensitive *S. aureus* (MSSA) is of concern, oral dicloxacillin (500 mg four times daily) or oral cephalexin (250 to 500 mg four times daily) for a 10-day course.

Treatment for cellulitis should always cover *Streptococcus*[3] and MSSA, with coverage for MRSA recommended for children, athletes, residents of long-term care facilities, military recruits, prisoners, patients with prior MRSA exposure, men who have sex with men, and intravenous drug users. In general, oral antibiotic regimens are as effective as intravenous regimens.[A4] Options include oral cephalexin (250 to 500 mg four times daily for 10 to 14 days),[A5] clindamycin (300 mg three times daily for 10 days), or trimethoprim-sulfamethoxazole (160 mg/800 mg twice daily for 10 days),[A6] depending on the suspected pathogens, the host, and the severity of systemic toxicity. Penicillin (250 mg twice daily) can be effective in preventing recurrent cellulitis. Intravenous vancomycin plus intravenous cefepime (15 mg/kg twice daily and 2 g three times daily, respectively, until clinical response allows transition to oral medications) is reserved for severe infections and immunocompromised patients.

NECROTIZING FASCIITIS

Necrotizing fasciitis is usually caused by multiple organisms, including anaerobic streptococci. Its diagnosis requires a high index of suspicion, and it must be considered when patients have areas of painful violaceous induration or a foul-smelling discharge.[4]

FIGURE 408-4. Erysipelas of the face with well-demarcated erythematous plaques. (Courtesy Yale Dermatology Residents' Slide Collection.)

TREATMENT

Prompt surgical débridement and broad-spectrum systemic antibiotics (e.g., a β-lactam/β-lactamase inhibitor such as piperacillin-tazobactam, 4.5 g IV every 6 hours for a total of 18 g/day [16 g piperacillin/2 g tazobactam] plus vancomycin [15 mg/kg IV twice daily]) is required. For patients with a β-lactam allergy, ciprofloxacin (500 mg PO or 400 mg IV twice daily), metronidazole (500 mg IV three times daily), and vancomycin (15 mg/kg IV twice daily) is an alternative regimen. Unless only a single organism is seen on Gram stain and isolated on culture, broad-spectrum antibiotic coverage should be continued because of the polymicrobial nature of necrotizing fasciitis and the difficulty of culturing anaerobes.

ERYTHRASMA

Although *Clostridium perfringens* can cause anaerobic cellulitis and gas gangrene, the most common cutaneous infection by gram-positive bacilli is erythrasma, which manifests as interdigital toe web maceration with fissures as well as shiny or scaly brown-red patches in the axillae and groin. The latter is often confused with tinea cruris (Chapter 405) and seborrheic dermatitis. A diagnostic finding is the presence of coral (orange-pink) fluorescence on Wood lamp illumination (ultraviolet A). The responsible organism is *Corynebacterium minutissimum*.

TREATMENT

Treatment options include topical and oral erythromycin (e.g., 333 mg three times daily for 7 to 14 days).

TOXIC ERYTHEMAS

Eruptions caused by the release of toxins (e.g., exfoliative toxins ET-A and ET-B, erythrogenic toxin) produced by *S. aureus* and streptococci include

staphylococcal scalded skin syndrome (Chapters 267 and 406), scarlet fever (Chapter 269), and toxic shock syndrome (Chapter 406). Staphylococcal scalded skin syndrome (see Fig. 406-19 in Chapter 406) is characterized by large areas of tender erythema in which superficial desquamation (peeling) develops, often with scaling and crusting in a radial array around the mouth. The areas of erythema are sterile; the conjunctivae, nasopharynx, or a distant site on the skin is the usual site of the primary staphylococcal infection. A clue to the diagnosis of scarlet fever is the presence of a strawberry tongue with prominent red papillae. Management involves treatment of the systemic infection (Chapters 267 and 406).

NEISSERIA INFECTIONS

Both gonococcemia (Chapter 275) and meningococcemia (Chapter 274) can manifest with cutaneous lesions. The former gives rise to a small number of vesicopustules on an erythematous base, generally acral in location (Fig. 408-5); these lesions represent septic emboli and are accompanied by fever, arthritis, and tenosynovitis. The earliest lesions of acute meningococcemia may be subtle (macular areas of erythema), but central hemorrhage (petechiae and purpura) and necrosis (gun-metal gray color) soon follow (Fig. 408-6). When accompanied by disseminated intravascular coagulation, large areas of retiform purpura and severe peripheral ischemia may develop. Cutaneous involvement in chronic meningococcemia is a reflection of lymphocytic or leukocytoclastic vasculitis. Management is systemic treatment (Chapters 274 and 275).

FIGURE 408-6. Purpuric and necrotic embolic lesions of meningococcemia. (Courtesy Yale Dermatology Residents' Slide Collection.)

PSEUDOMONAS INFECTIONS

Pseudomonas infections of the skin vary from "hot tub" folliculitis (Chapter 406) to soft tissue infections of the external ear. Interdigital toe web infections that begin as simple tinea pedis can be complicated by superimposed *Pseudomonas* infection and result in erythema, swelling, tenderness, and drainage. Depending on its severity, treatment varies from topical antiseptics to oral or intravenous fluoroquinolones (e.g., ciprofloxacin, 500 mg PO twice daily for 7 to 14 days). In immunocompromised hosts, *Pseudomonas* and other gram-negative bacilli can produce cellulitis as well as secondary septic emboli in the skin. The latter begin as purpura or purpuric bullae in which central necrosis then develops. These lesions, which arise as a result of ischemic infarction of the skin, are termed *ecthyma gangrenosum*. Management is treatment of the systemic pseudomonal disease (Chapter 282).

SPIROCHETES

Spirochetal infections have a wide range of skin findings, from erythema migrans secondary to *Borrelia burgdorferi* (Chapter 296), to endemic treponematoses such as yaws and pinta (Chapter 295), to the cutaneous manifestations of the three stages of syphilis (Chapter 295). Syphilitic lesions include a firm, generally nontender ulceration (chancre) in primary syphilis; a generalized papulosquamous eruption plus alopecia, oral ulcers, and condylomata lata in secondary syphilis; and thick plaques and ulcers in tertiary disease (Chapter 405). Management involves treatment of the systemic disease.

MYCOBACTERIA INFECTIONS

Infections with *Mycobacterium tuberculosis* and mycobacteria other than *M. tuberculosis* (atypical mycobacteria) are associated with skin lesions, including verrucous or crusted papules, erythematous nodules, scarring granulomatous plaques, and draining ulcers. In immunocompetent hosts in high-income countries, *Mycobacterium marinum* (Chapter 300) is most commonly associated with skin disease, which usually manifests in a lymphocutaneous (i.e., sporotrichoid) pattern. Lower extremity furunculosis due to atypical mycobacteria can occur following pre-pedicure footbaths, and mesotherapy or injection of tattoo ink contaminated with *Mycobacterium chelonae* can lead to erythematous papules. Treatment of cutaneous mycobacterial disease is the same as for systemic disease (Chapters 299 and 300).

VIRAL INFECTIONS

The most common viral infections of the skin are verrucae (warts; see Fig. 406-3 in Chapter 406), recurrent oral and genital herpes simplex (Chapters 345 and 406), molluscum contagiosum (see Fig. 407-9 in Chapter 407), and exanthems (Chapter 406). Varicella and herpes zoster are seen less frequently (Chapter 346). Patients with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Chapter 336) can develop alopecia, maculopapular eruptions, vesicles, urticarial lesions, or, with severe disease, even retiform purpura with necrosis.[5]

FUNGAL INFECTIONS

A variety of fungal infections involve the skin and nails and are most commonly due to dermatophytes (tinea), *Candida* spp, and *Malassezia* spp (pityriasis versicolor, also referred to as tinea versicolor) (Chapter 405; also see Table 408-1). Although both dermatophyte infections and pityriasis versicolor are associated with scaling, cutaneous candidiasis is characterized by erythema, a more erosive appearance, and satellite pustules. Treatment is described in Chapter 405.

Septic emboli caused by *Candida* or other opportunistic fungi such as *Aspergillus* (Chapter 311) or *Fusarium* often have a clinical appearance similar to that of ecthyma gangrenosum secondary to gram-negative bacilli such as *Pseudomonas*. The responsible organisms can be detected histologically in biopsy specimens or by bedside examination of dermal scrapings; culture confirms the specific organism. Although rare, cutaneous plaques secondary to *Pneumocystis jiroveci* favor the external ear canal. Treatment is for the underlying fungal infection.

ECTOPARASITES AND PARASITES

ECTOPARASITES: SCABIES AND LICE

The most common ectoparasitic cutaneous infestations are (1) scabies from the human variant of the *Sarcoptes* mite; and (2) lice, of which there are three subtypes: head, body, and pubic (Chapter 98). Scabies is characterized by pruritus in association with papules, papulovesicles, and linear burrows as well as signs of scratching, such as excoriations and areas of dermatitis. Sites of predilection include the wrists, ankles, fingers, and toes (including the web spaces), areolae, and genitalia (especially the penis) (Fig. 408-7). The number of mites living within the stratum corneum is limited in immunocompetent hosts; when scraped and examined microscopically,

FIGURE 408-7. Scabies with involvement of the penis. (From Bolognia JL, Jorizzo JL, Schaffer JV, eds. *Dermatology*, 3rd ed. London: Elsevier; 2012.)

linear burrows provide the highest yield of mites and eggs. In elderly and immunosuppressed patients, a form of scabies known as crusted (previously Norwegian) scabies manifests as multiple areas of scaling and crusting that are teeming with mites.

Infestations with scalp lice are seen most commonly in children, who may be symptom free or have marked pruritus. In addition to the lice, multiple egg casings ("nits") are attached to the proximal portions of scalp hairs. In high-income countries, body lice are seen primarily in homeless individuals; patients typically have multiple erythematous papules at the sites of bites as well as signs of scratching. The lice and their eggs are found in the patient's clothing. Pubic lice are sometimes called "crabs" because their bodies are shorter and broader than those of scalp or body lice and thus resemble the shape of a crab. Because of their leg span, these lice reside primarily on pubic hairs and less often on axillary hairs or eyelashes.

TREATMENT

First-line treatments for head lice, pubic lice, and routine scabies are topical 0.5% malathion lotion or gel, 5% permethrin cream, and 5% permethrin cream, respectively; each of these topical medications is applied for 8 to 12 hours on days 1 and 8. Topical ivermectin 0.5% lotion is also approved for the treatment of head lice. Two applications of a neem extract–containing shampoo is another potential option.[A7] For crusted scabies, epidemic outbreaks of scabies (e.g., in nursing homes), or difficult-to-treat head lice, oral ivermectin (200 to 400μg/kg; off-label use) can eradicate the infestation. Treatment of body lice involves discarding egg- and lice-infested clothing; for head lice, potential sources of reinfection, such as hairbrushes, should be discarded. Sexual and household contacts of patients with pubic lice and scabies, respectively, must be treated similarly to the patient who has symptoms.

OTHER PARASITES

Cutaneous lesions are seen in leishmaniasis (Chapter 319), amebiasis (Chapter 323), schistosomiasis (Chapter 326), onchocerciasis (Chapter 327), strongyloidiasis (Chapter 327), and hookworm infections (Chapter 327). Exposure to water infested with the cercariae of animal schistosomes results in multiple erythematous papules, which occur most commonly on the feet and are termed *swimmer's itch*. Dog and cat hookworm infections lead to cutaneous larva migrans, with serpiginous erythematous tracks that correspond to the path of migration of the hookworm larvae in sites where there has been direct contact with infected sand, most commonly the feet. Both of these infections are self-limited because the parasite's life cycle cannot be completed in humans. In immunocompromised hosts, cutaneous plaques can occasionally develop from free-living amebae such as *Acanthamoeba*.

TABLE 408-2 DISORDERS OF PIGMENTATION

HYPOPIGMENTATION
Diffuse (Pigmentary Dilution)

*Often referred to as *vitiligo* or *vitiligo-like* in the oncologic literature.
POEMS = *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal protein, *s*kin changes.

DISORDERS OF HYPOPIGMENTATION AND HYPERPIGMENTATION

Disorders of pigmentation can be divided into four major categories: diffuse, linear, circumscribed, and either reticulated (in the case of hyperpigmentation) or guttate (in the case of hypopigmentation) (Table 408-2).

HYPOPIGMENTATION

ALBINISM

For diffuse hypopigmentation, the primary disorder is oculocutaneous albinism, an autosomal recessive disorder in which there is a pigmentary dilution of melanin-containing structures (i.e., the eyes, hair, and skin). The phenotype varies from total absence of melanin pigment to a subtle decrease whose

recognition requires comparison with first-degree relatives; the density of melanocytes in skin is normal, but their ability to produce pigment is absent or decreased. Ninety percent of patients with oculocutaneous albinism have mutations in the genes that encode either tyrosinase (type I) or P protein (type II). Complications of oculocutaneous albinism include decreased visual acuity, nystagmus, photophobia, and an increase in cutaneous carcinomas, especially squamous cell carcinoma. These signs and symptoms are most severe in those who produce the least pigment and have the greatest amount of cumulative sun exposure. The differential diagnosis includes total vitiligo (absence of melanocytes histologically) and a few inborn errors of metabolism (e.g., phenylketonuria). Treatment consists of longitudinal ophthalmologic care and minimizing sun exposure.

LINEAR HYPOPIGMENTATION

Disorders of linear hypopigmentation consist primarily of nevoid conditions caused by somatic mosaicism (e.g., linear nevoid hypopigmentation, segmental pigmentation disorder), in which streaks of hypomelanosis follow the lines of Blaschko or patients have a blocklike configuration of hypopigmented patches. A minority of patients have associated central nervous system, musculoskeletal, or ocular abnormalities.

CIRCUMSCRIBED (PATCHY) HYPOPIGMENTATION

Vitiligo

Vitiligo (Fig. 408-8) is usually slowly progressive and occurs principally in periorificial areas (around the eyes, nose, lips, genitalia) and on the hands, feet, flexor surface of the wrists, ankles, elbows, and knees and in major body folds. Vitiligo, which is caused by a loss of melanocytes within the skin, is also associated with autoimmune endocrinopathies and alopecia areata.

The differential diagnosis is primarily chemical leukoderma secondary to compounds that are cytotoxic to melanocytes (e.g., catechols, phenols), drug-induced leukoderma (e.g., caused by imatinib), the leukoderma of melanoma (a good prognostic sign if seen in association with immunotherapy but an indication to exclude metastases if occurs spontaneously), and the leukoderma of scleroderma with retention of perifollicular pigmentation. In patients with vitiligo, T cells that recognize antigens on the surface of melanocytes (and melanoma cells) are found within the skin and in peripheral blood.

TREATMENT

Treatment of vitiligo includes topical corticosteroids, topical immunomodulators (e.g., ruxolitinib,[A8] tacrolimus), and photo-therapy.[A9] Combinations of follicular and epidermal stem cell suspensions are an experimental approach for difficult-to-treat disease.[A10,A11]

GUTTATE HYPOPIGMENTATION

Idiopathic guttate hypomelanosis, in which there are well-demarcated hypopigmented macules usually measuring 2 to 4 mm in diameter, is the most common cause of guttate ("raindrop") leukoderma (Fig. 408-9). The favored sites for this common age-related disorder, which may be related to chronic sun exposure, are the shins and the extensor surface of the forearms.

FIGURE 408-8. Striking leukoderma of the hand in a patient with vitiligo. In well-developed lesions, the skin is white, not tan, in color due to complete loss of melanin.

OTHER ACQUIRED CAUSES

Circumscribed hypomelanosis is seen in patients with pityriasis (tinea) versicolor (see Fig. 405-29 in Chapter 405) and postinflammatory hypopigmentation. Although postinflammatory hypopigmentation is most often associated with atopic dermatitis, it also can occur with sarcoidosis (Chapter 83), cutaneous lupus erythematosus (Chapter 245), and mycosis fungoides (Chapter 171).

CONGENITAL CAUSES

Congenital circumscribed areas of hypomelanosis include *nevus depigmentosus,* a common tan "birthmark" seen in 1 in 50 infants in whom there is a partial decrease in pigment; *piebaldism,* an unusual autosomal dominant disorder with areas of complete absence of pigment caused by mutations in the *KIT* gene; *nevus anemicus,* a localized area of vasoconstriction; and the *ash-leaf spots* of tuberous sclerosis (Chapter 385), with a partial decrease in pigment.

HYPERPIGMENTATION

DIFFUSE HYPERPIGMENTATION

Diffuse hyperpigmentation is most commonly due to drugs (e.g., cyclophosphamide, zidovudine) and endocrinopathies associated with increased circulating levels of adrenocorticotropic hormone (ACTH) (e.g., Addison disease [Chapter 208], ectopic ACTH production by tumors such as small cell lung carcinoma [Chapter 177]). ACTH, as well as melanocyte-stimulating hormone, can bind and activate the melanocortin-1 receptors on melanocytes, thereby leading to increased melanin production. Additional causes include hemochromatosis (Chapter 196), systemic sclerosis (Chapter 246), primary biliary cirrhosis (Chapter 141), POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal protein, *s*kin changes) (Table 408-3), and hyperthyroidism (Chapter 207). Systemic exposure to silver (argyria; Chapter 20) can lead to a slate-gray color.

LINEAR AND RETICULATED HYPERPIGMENTATION

Linear streaks of hyperpigmentation can be due to nevoid conditions that reflect cutaneous mosaicism, as in linear hypopigmentation (see earlier) or several genodermatoses (e.g., incontinentia pigmenti, which is an X-linked dominant disorder caused by mutations in the gene *NEMO*), or they can be due to exposure to either plant-derived psoralens (e.g., from limes) plus ultraviolet A irradiation or systemic bleomycin (flagellate pigmentation). Reticulated hypermelanosis is also seen in several genodermatoses (e.g., dyskeratosis congenita) and after chronic exposure to heat (erythema ab igne). The latter corresponds to the cutaneous venous plexus and is seen most commonly in the lumbosacral region where heating pads have been applied or on the anterior thighs from laptop computers.

CIRCUMSCRIBED (PATCHY) HYPERPIGMENTATION

The most common causes of circumscribed hypermelanosis are pityriasis (tinea) versicolor (which can present as both hypopigmentation and hyperpigmentation, hence its name), postinflammatory hyperpigmentation, and melasma. Postinflammatory hyperpigmentation (Fig. 408-10) is observed more frequently in darkly pigmented individuals and often follows acne vulgaris, arthropod bites, chronic dermatitis, and lichen planus.[6] Additional causes of circumscribed darkening of the skin are cutaneous mastocytosis (urticaria pigmentosa; Chapter 235), deposits of drugs such as antimalarials and minocycline (blue-gray discoloration), and medications that produce fixed drug reactions, most frequently trimethoprim-sulfamethoxazole and nonsteroidal anti-inflammatory drugs. In melasma (Fig. 408-11), symmetrical hyperpigmented patches are seen on the lateral aspect of the forehead, upper part of the cheek, and mandibular area. At least 90% of patients with melasma are women. The lesions are exacerbated by ultraviolet light and estrogen (oral contraceptives, pregnancy).

TREATMENT

Melasma is treated with daily broad-spectrum sunscreens plus lightening agents such as hydroquinone (4% cream) and retinoic acid (0.025 to 0.1% cream) for 3 to 4 months, often in combination with mild topical corticosteroids to reduce irritation[7]; if irritation develops, the creams are discontinued temporarily and then restarted at a reduced frequency.

DISTINCTIVE LESIONS IN BLACK SKIN

Although some diseases are more common in patients of African ancestry (e.g., tinea capitis, pseudofolliculitis barbae, dissecting cellulitis), others are simply more noticeable (e.g., vitiligo and postinflammatory hypopigmentation) (Table 408-4). The explanation for the increased incidence is speculative in most instances, with the exception of curled hairs leading to pseudofolliculitis barbae. Individuals with polymorphisms in the gene that encodes KRT75 are more likely to develop this condition. Tightly curled hairs, when shaved, are usually cut at an oblique angle, which results in a sharp tip at the distal end of the hair shaft that allows penetration of the skin adjacent to the hair follicle and subsequent inflammation. The patient can apply topical anti-inflammatory agents, avoid shaving, or undergo laser hair removal. Some cutaneous disorders are seen less commonly in Black skin (e.g., acne rosacea and scabies).

Keloids

Another entity seen more commonly in individuals of African descent is keloids (Fig. 408-12). Keloids generally appear at sites of trauma (e.g., ear piercing) but may occasionally develop spontaneously, especially on the trunk. In the former situation, they are thought to represent an exaggerated response to wound healing, with increased formation of collagen not only at the site of the trauma (as in hypertrophic scars) but also in adjacent, previously uninvolved skin.

Ulcers secondary to sickle cell anemia
GENERALIZED
Post-inflammatory hyperpigmentation and hypopigmentation
Keloids
Cutaneous sarcoidosis, hypopigmented mycosis fungoides, lichen planus pigmentosus
Papular eczema and follicular-based inflammation

*Also previously termed follicular degeneration syndrome or hot comb alopecia.

FIGURE 408-12. Acne keloidalis in an African American man. (Courtesy Kalman Watsky, MD.)

TREATMENT

Treatment options include intralesional corticosteroids, intralesional 5-fluorouracil,[A12] intralesional interferon, pulsed dye laser, cryotherapy, or excision followed by low-dose radiation therapy.[8] Recently, verteporfin was found to block transcription of *En1* (engrailed-1) in murine dermal fibroblasts and to prevent wound-induced collagen deposition and scarring.[9] However, verteporfin may not be effective in keloids, which exhibit cellular proliferation not just enhanced production of extracellular matrix.

REGIONAL DERMATOSES

Some common dermatoses have a predilection for particular anatomic sites (Fig. 408-13 and Table 408-5). These locations can help narrow the differential and guide further diagnostic testing and therapy in many patients. The most common association is insulin resistance.

One regional dermatosis is acanthosis nigricans (Fig. 408-14).[10] Because of its potential systemic implications, careful medical evaluation is required (Table 408-6).

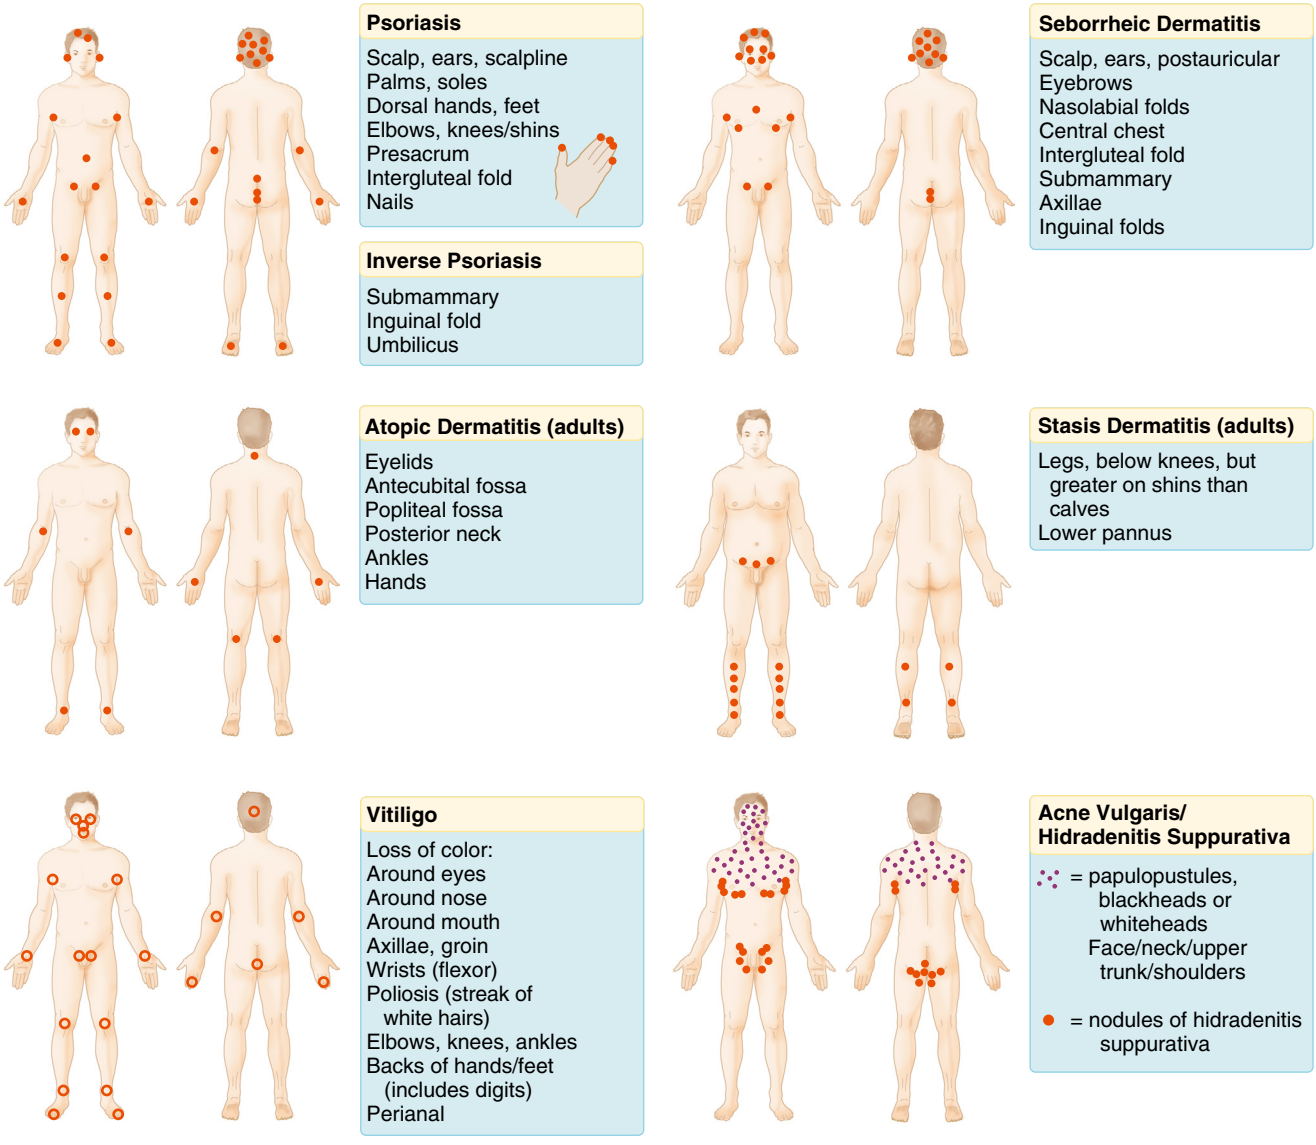

FIGURE 408-13. Regional involvement of specific skin diseases.

TABLE 408-5 REGIONAL DERMATOLOGY

REGION OF SKIN	TYPE OF SKIN LESION	DISEASE PROCESS
Scalp	Papulosquamous and eczematous	Seborrheic dermatitis, psoriasis, tinea capitis, eczema (atopic, contact [especially hairline])
	Pustular	Folliculitis, kerion
	Papulonodular	Melanocytic nevi, seborrheic keratoses, pilar cysts, verrucae, cherry angiomas, actinic keratoses (bald scalp)
Face	Pustular	Acne, rosacea, folliculitis (beard), tinea, demodicosis
	Papulosquamous and eczematous	Seborrheic dermatitis, psoriasis (hairline), contact dermatitis (e.g., cosmetics), atopic dermatitis, pityriasis alba, impetigo, systemic lupus erythematosus, photodermatitis
	Vesicular	Herpes simplex, herpes zoster, bullous impetigo
	Papulonodular	Melanocytic nevi, seborrheic keratoses, actinic keratoses, sebaceous hyperplasia, basal cell carcinomas, squamous cell carcinomas, melanomas
	Atrophic and telangiectatic	Discoid lupus erythematosus
Trunk	Papulosquamous and eczematous	Psoriasis, atopic dermatitis, contact dermatitis, tinea versicolor, pityriasis rosea, scabies, secondary syphilis, subacute cutaneous lupus (upper trunk)
	Vesiculobullous	Herpes zoster, bullous pemphigoid, pemphigus, erythema multiforme, Stevens-Johnson syndrome
	Maculopapular	Morbilliform drug reactions, viral exanthems
	Papulonodular	Melanocytic nevi, seborrheic keratoses, cherry angiomas, lipomas, epidermoid inclusion cysts, basal and squamous cell carcinomas, keloids, neurofibromas, melanoma
	Pustular	Acne, folliculitis
	Urticarial	Hives, drug reactions, early herpes zoster
Arms and forearms	Eczematous and papulosquamous	Contact dermatitis (e.g., plants), atopic dermatitis, psoriasis, lichen planus, photodermatitis (drugs, contactants, dermatomyositis, subacute cutaneous lupus)
	Papulonodular	Melanocytic nevi, verrucae, seborrheic keratoses, actinic keratoses, squamous cell carcinomas, polymorphic light eruption, rheumatoid nodules (elbows), xanthomas (elbows)
	Purpuric	Actinic (solar) purpura
	Annular	Granuloma annulare, subacute cutaneous lupus
Legs	Eczematous and papulosquamous	Stasis dermatitis, eczema craquelé (xerotic eczema), contact dermatitis, atopic dermatitis, psoriasis, lichen planus
	Papulonodular	Melanocytic nevi, dermatofibromas, erythema nodosum, melanoma, xanthomas (knees, Achilles tendon), Kaposi sarcoma
	Annular	Tinea, granuloma annulare
	Purpuric	Capillaritis, vasculitis
	Ulcerative	Stasis ulcers, arterial insufficiency, trauma, pyoderma gangrenosum, livedoid vasculopathy, squamous cell carcinoma, diffuse dermal angiomatosis
Genitalia and groin	Eczematous and papulosquamous	Seborrheic dermatitis, tinea, candidiasis, psoriasis, contact dermatitis, lichen simplex chronicus, scabies, reactive arthritis (Reiter syndrome), erythrasma, lichen planus
	Vesiculobullous	Herpes simplex
	Ulcerative	Herpes simplex, trauma, syphilis, chancroid, Behçet disease, squamous cell carcinoma
	Papulonodular	Angiokeratomas, epidermoid inclusion cysts, molluscum contagiosum, condyloma acuminata, hidradenitis suppurativa, squamous cell carcinoma
	Pustular	Folliculitis, candidiasis, hidradenitis suppurativa
Hands	Eczematous and papulosquamous	Irritant and allergic contact dermatitis, atopic dermatitis, tinea, scabies, secondary syphilis
	Vesiculobullous, pustular	Dyshidrotic eczema, psoriasis (palmar), hand-foot-and-mouth disease (palmar), herpetic whitlow, blistering dactylitis, porphyria cutanea tarda (dorsal), erythema multiforme, Stevens-Johnson syndrome, *Mycoplasma pneumoniae*/respiratory infection-induced rash and mucositis, epidermolysis bullosa acquisita
	Papulonodular	Warts, actinic keratoses (dorsal), digital mucous cysts (dorsal fingers), squamous cell carcinomas (dorsal), granuloma annulare, pyogenic granuloma
	Depigmentation	Vitiligo, chemical leukoderma
	Proximal nailfold telangiectases	Systemic sclerosis, dermatomyositis, systemic lupus erythematosus, Osler-Weber-Rendu disease
Feet	Eczematous and papulosquamous	Tinea, psoriasis, contact dermatitis, atopic dermatitis, syphilis (plantar)
	Vesiculobullous	Tinea, arthropod bites, epidermolysis bullosa (inherited and acquired), erythema multiforme, hand-foot-and mouth disease (plantar)
	Papules	Verrucae (plantar), corns, perniosis
	Ulcerative	Neuropathic ulcers (plantar)

FIGURE 408-14. Acanthosis nigricans of the axilla. Note the velvet-like appearance of the skin. (Courtesy Yale Dermatology Residents' Slide Collection.)

TABLE 408-6 CLUES TO UNDERLYING SYSTEMIC CONDITIONS ASSOCIATED WITH ACANTHOSIS NIGRICANS

Polycystic ovary syndrome	Women with acne, hirsutism, and/or menstrual irregularities
Malignancy	Sudden onset, weight loss, inflamed seborrheic keratoses, tripe palms
Endocrinopathy	Insulin resistance, type 2 diabetes, Cushing syndrome (striae, hypertension, central obesity, buffalo hump), hypothyroidism
Drug-induced	Especially niacin, human growth hormone, oral contraceptive agents, corticosteroids, protease inhibitors

409 DISEASES OF HAIR AND NAILS

ANTONELLA TOSTI

HAIR DISORDERS

Normal Hair

The hair shaft is a fully keratinized structure that is produced by the hair follicle. The entire skin, with the exception of the palms and soles, contains hair follicles. Hair follicles are of two types: terminal follicles and vellus follicles. Terminal follicles, which reach the hypodermis, produce terminal hairs, which are long, thick (60 to 80 μm), and pigmented. Terminal hairs are present since birth on the scalp, eyebrows, and eyelashes and later develop after puberty on the axillae, pubis, and beard region in males. Vellus follicles are small and localized to the superficial dermis and mid-dermis, where they produce vellus hairs, which are thin (<30 μm), short (<2 cm), and not pigmented and cover all the glabrous skin.

The hair follicle is formed by an upper permanent portion and a lower dynamic transient portion that migrates during the hair cycle. The transient portion includes the hair bulb, which is surrounded by the dermal papilla and contains the hair matrix that produces the hair shaft and its sheaths. The anatomic division between the permanent and the transient portion is just below the bulge region, which corresponds to the insertion of the erector pili muscle. The bulge region contains the epithelial stem cells that regenerate the follicle in each hair growth cycle; its damage results in stem cell destruction and cicatricial alopecia.

Hair Cycle

Hair follicles have a cyclic activity, characterized by alternating periods of hair shaft production and periods of resting (anagen, catagen, telogen). During the anagen phase, the follicles produce the hair shaft. Duration of anagen, which in the scalp ranges from 2 to 7 years, determines hair shaft length. Maximal length and growth rate of terminal hair varies in the different body regions. Scalp hair grows approximately 0.4 mm/day and may reach a length of more than 1 m. Maximal hair length decreases with age. During telogen, hair production is absent, even if the shaft remains within the follicle to be shed only when, after 3 months, the follicle reenters the anagen phase.

The hair cycle of adjacent scalp follicles is not synchronized. In normal conditions, approximately 85 to 90% of follicles are in anagen and 10 to 15% in telogen.

Hair Loss and Alopecias

Hair loss distresses most patients, independently from its severity and pattern. In some cases, the decrement in quality of life attributable to hair loss is comparable with that caused by major chronic diseases. Because some causes of hair loss are readily treatable, accurate diagnosis is critical.

The first diagnostic step is to assess family history, drug intake, systemic illness, and severity and duration of hair loss (Table 409-1). The second step is to establish whether the hair density is normal or decreased. The third step is to evaluate whether the rate of hair shedding is normal or increased. Acute and severe hair loss is typical of diseases that interrupt the mitotic activity of anagen follicles (drugs, alopecia areata). A normal hair density suggests telogen effluvium, which may be acute or chronic. A reduced hair density may involve the whole scalp (diffuse alopecia), may manifest with bald patches (patchy alopecia), or may be limited to specific scalp regions (patterned alopecia, marginal alopecia). In patchy alopecias, the scalp may show patches of alopecia that are completely devoid of hairs (alopecia areata, cicatricial alopecia) or have short broken hairs (trichotillomania, hair shaft disorders).[1] Dermatoscopy is a rapid, noninvasive technique that greatly improves the clinical diagnosis of alopecias and hair shaft disorders in adults and children (Table 409-2).

TABLE 409-1 CAUSES OF HAIR LOSS

DIFFUSE ALOPECIA
Telogen effluvium (e.g., after illness or stress)
Anagen effluvium (e.g., after chemotherapy or radiation therapy)
Medications (see Table 409-3)
Nutritional deficiency
Hair treatments
Androgenetic alopecia (in women)
Hormonal changes (e.g., menopause, discontinuation of oral contraceptives, hypothyroidism)
PATCHY ALOPECIA
Alopecia areata (probably autoimmune)
Cicatricial (scarring) alopecia (e.g., lichen planopilaris, discoid lupus erythematosus, folliculitis decalvans, central centrifugal cicatricial alopecia)
Traction alopecia (e.g., excessive hair straightening or braiding)
Trichotillomania (hair pulling)
Scalp infection (e.g., ringworm)
MARGINAL ALOPECIA
Frontal fibrosing alopecia
Traction alopecia
Alopecia areata (ophiasis variant)

TABLE 409-2 DERMATOSCOPIC SIGNS IN HAIR AND SCALP DISORDERS

Alopecia areata	Yellow dots, exclamation mark hairs, broken hairs
Androgenetic alopecia	>20% variability in the hair diameter
Lichen planopilaris/frontal fibrosing alopecia	Peripilar casts; loss of follicular openings
Trichotillomania	Broken hairs, question mark hairs
Tinea capitis	Comma hairs, corkscrew hairs
Discoid lupus erythematosus	Red dots, follicular plugs
Folliculitis decalvans	Hair tufts
Scalp psoriasis	Coiled capillaries
Seborrheic dermatitis	Arborizing vessels

ABSTRACT

This chapter reviews the most important diseases of hair and nails encountered in medical practice. The reader will be able to understand different types of non-scarring and scarring alopecias. Differential diagnosis and updated diagnostic methods are discussed in detail together with optimal treatment approaches. Hair manifestation of systemic disorders including drug-induced hair loss are also discussed. The part on nails describes traumatic, inflammatory, and infective nail disorders with tips for correct diagnosis and optimal treatment. Nail manifestation of systemic disorders are also discussed.

KEYWORDS

alopecia areata
androgenetic alopecia
telogen effluvium
anagen effluvium
frontal fibrosing alopecia
trichotillomania
scarring alopecias
hirsutism
clubbing
Beau lines
paronychia
onychomycosis

TELOGEN EFFLUVIUM

ACUTE TELOGEN EFFLUVIUM

Acute telogen effluvium results from noxious events that precipitate the entry of a large number of follicles into their resting phase (telogen). Possible causes include systemic diseases, drugs (Table 409-3), fever, stress, weight loss, delivery, iron deficiency, and inflammatory scalp disorders. Severe telogen effluvium also is common 2 to 3 months after infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and may be associated with scalp paresthesia or pain (trichodynia).[2,3] For drugs, the severity of hair loss depends on the drug, its dosage, and the patient's susceptibility.

Hair loss starts approximately 3 months after the causative event, a time frame that corresponds with the duration of the telogen phase. Telogen hairs are retained within the follicle during telogen, to be shed when the follicle produces a new anagen hair. Hair loss is severe when 100 to 200 hairs are shed daily. The patient usually remembers precisely when the increased shedding began. Acute telogen effluvium does not usually produce visible alopecia because approximately 50% of hairs need to be lost before reduction of hair density is evident.

CHRONIC TELOGEN EFFLUVIUM

Chronic telogen effluvium mostly affects middle-aged women and frequently remains unexplained. The daily shedding is mild (<100 hairs daily), but patients are distressed and complain of progressive temporal thinning as well as decreased hair mass and volume. Scalp pain (trichodynia) is frequently reported. Patients who have a high hair density may bring in envelopes of shed hairs to prove the amount of hair loss. There is no effective treatment. Chronic telogen effluvium has a chronic course with periodic exacerbations.

TREATMENT AND PROGNOSIS

Acute telogen effluvium subsides spontaneously in a few months after removal of the cause. It may, however, unmask or aggravate androgenetic alopecia.

DIFFUSE ALOPECIA

ANAGEN EFFLUVIUM

Acute hair shedding leading to diffuse alopecia is a typical side effect of cancer chemotherapy and scalp radiation. Hair loss is acute and severe and may produce loss of most of the scalp hair, eyebrows, and eyelashes; other body hairs are less commonly involved. Hair shedding usually starts 4 to 6 weeks after drug intake with up to 1000 hairs shed daily. Regrowth is usually fast after discontinuation of therapy, but hair shape and color may be different. Permanent alopecia may occur with high-dose radiation and certain drug regimens, such as busulfan and docetaxel.[4]

Scalp hypothermia prevents or reduces hair loss during chemotherapy,[A1] and can prevent permanent alopecia after docetaxel regimens[5] Topical minoxidil accelerates hair regrowth but does not prevent hair loss.

PATTERNED ALOPECIA (ANDROGENETIC ALOPECIA)

Androgenetic alopecia, which is the most common form of hair loss, affects up to 80% of men and 50% of women in the course of their life. Androgenetic alopecia is caused by a progressive reduction in the diameter, length, and pigmentation of the hair. Hair thinning is not diffuse, but rather is limited to the frontal, temporal, and vertex areas, where hair follicles are sensitive to the effects of the testosterone metabolite dehydrotestosterone (DHT). This sensitivity to DHT, which requires the 5α-reductase enzymes, is genetically determined. In men, androgenetic alopecia involves the frontotemporal areas and the vertex, following a pattern that corresponds to the Hamilton-Norwood scale. In women, androgenetic alopecia produces diffuse thinning of the crown region with maintenance of the frontal hairline (Ludwig pattern), a pattern that can easily be appreciated by making a central parting and comparing hair density at the top with hair density at the occipital region. In premenopausal women, androgenetic alopecia can be a sign of hyperandrogenism, together with hirsutism and acne. In most women, however, it occurs in the absence of biochemical and clinical evidence of androgen excess and may be due to excessive follicular sensitivity to androgens. Data also show that patients with androgenetic alopecia may be at increased risk for dying from diabetes and heart disease.

TABLE 409-3 DRUGS REPORTED TO INDUCE HAIR LOSS

ACE inhibitors (captopril, enalapril, moexipril, ramipril)
Allopurinol
Amiodarone
Amphetamines*,†
Analgesics, anti-inflammatories (ibuprofen, indomethacin, naproxen)
Androgens*,†
Anticoagulants (coumarin, dextran, heparin/heparinoids apixaban, dabigatran, rivaroxaban)*,†
Antiepileptics (carbamazepine, hydantoins, lamotrigine, troxidone, valproic acid, vigabatrin)*,†
Antipsychotics (flupenthixol decanoate, fluphenazine decanoate)
Antithyroid drugs (carbimazole, iodine, thiouracil)*
Appetite suppressants
Aromatase inhibitors (fadrozole, formestane [4-OHA], vorozole)*,†
Benzimidazoles (albendazole, mebendazole)
β-Blockers (levobunolol, metoprolol, nadolol, propranolol, timolol)*
Bromocriptine
Buspirone
Busulfan§
Butyrophenones
Cantharidin
Cholestyramine
Chloramphenicol
Cidofovir
Cimetidine
Clonazepam
Clotrimazole
Colchicine
Contraceptives (oral)
Danazol
Diclofenac
Dixyrazine
Diazoxide
Docetaxel§
Ethambutol
Ethionamide
Fibrates (clofibrate, fenofibrate)
Gentamicin
Gefitinib‖
Glatiramer acetate
Glibenclamide
Gold salts
Granulocyte colony-stimulating factor
Haloperidol
Immunoglobulins
Indanediones

Retinoids (acitretin, etretinate, isotretinoin)*,†
Risperidone
Salicylates
Serotonin reuptake inhibitors (fluoxetine, fluvoxamine, paroxetine, sertraline)*
Sonidegib*,†
Sorafenib
Spironolactone
Strontium ranelate*,†
Sulfasalazine
Tamoxifen
Terbinafine
Terfenadine
Thiamphenicol
Thyroxine
Tocopherol (vitamin E)
Trazodone
Triazoles (fluconazole, itraconazole)
Tricyclic antidepressants (amitriptyline, desipramine, doxepin, imipramine, maprotiline)
Trimethadione
Triparanol
Vasopressin
Vismodegib*,†

*Established by multiple reports or proved by rechallenge.
†Hair loss usually severe.
‡May produce androgenetic alopecia.
§May produce permanent alopecia.
‖May produce anagen effluvium.
¶May produce telogen effluvium 3 months after discontinuation.
ACE = angiotensin-converting enzyme inhibitor.

TREATMENT

Androgenetic alopecia is a progressive disease that tends to worsen with time. Medical treatments include 2% topical minoxidil in women and 5% topical minoxidil and/or oral finasteride, 1 mg/day, in men.[A2] Finasteride topical spray is as effective as oral finasteride with less impact on dihydrotestosterone levels.[A3] Oral dutasteride, 0.5 mg, approved in some countries, is more effective than finasteride with a similar safety profile.[A4] Clinical improvement is mostly due to thickening of the preexisting hair. Some men may report a post-finasteride syndrome characterized by persistent sexual dysfunction and depression occurring after treatment with 5α-reductase inhibitors. Low dose oral minoxidil (0.25 to 2.5 mg/day) is effective and usually well tolerated.[6,7]

Treatments for androgenetic alopecia should be continued for at least 6 months before assessing efficacy, and regular drug use is mandatory for

maintaining results. Interruption of minoxidil produces an acute telogen effluvium, which becomes evident 3 to 4 months after interruption and cannot be prevented by concomitant finasteride treatment. Interruption of finasteride is followed by gradual hair loss, with return to the pretreatment status after 1 year. Hair transplantation is a good option for men with severe androgenetic alopecia, and treatment with finasteride, 1 mg/day, improves the long-term results of surgery. Hair transplantation in women is more complicated because the hair thinning is often diffuse in the parietal and occipital regions, so there is not a good hair donor area.

PATCHY ALOPECIA

ALOPECIA AREATA

Alopecia areata is a common form of nonscarring, usually patchy hair loss affecting up to 2% of the population. The etiology is unknown, but evidence is consistent with an autoimmune disease to which both a genetic predisposition and environmental factors contribute. In genetically predisposed individuals, various triggering factors cause a predominantly CD8-driven, T_H1-type T-cell reaction against the hair follicles, and the Janus kinase and signal transducer and activator of transcription (JAK/STAT) pathway has a main role in sustaining the autoimmune reaction, thereby resulting in acute hair loss.

Alopecia areata can start at any age, but severe forms often start during childhood and are more frequent in males.[8] Clinical examination reveals one or multiple well-circumscribed smooth patches of nonscarring absence of hair that enlarge in a centrifugal way (Fig. 409-1). The margins of the patches often show 3-mm-long broken hairs with a pigmented tip (exclamation mark hairs), which indicates disease progression.

Alopecia areata may affect all hairy body areas, including the eyebrows and eyelashes (Fig. 409-2). Severe forms involve the entire scalp (alopecia totalis) or all body hair (alopecia universalis). Involvement of the scalp margins (ophiasis) is associated with a poor prognosis. Alopecia areata may be associated with other autoimmune diseases, most commonly thyroid diseases (Chapter 207). Other possible associations include anxiety, depression,[9] celiac disease (Chapter 126), vitiligo (Chapter 408), and atopy (Chapter 405). Nail abnormalities are common, especially in children.

The natural history of alopecia areata is unpredictable. Studies indicate that 34 to 50% of patients will recover within 1 year and 15 to 25% will progress to alopecia totalis/universalis, a condition from which full recovery is only approximately 10%.

TREATMENT

A variety of treatments may induce temporary hair regrowth but do not change the long-term prognosis.[10] In the absence of many head-to-head comparisons, the preferred order of treatment is still evolving.

Intralesional steroids can be used in localized areas, including the eyebrows. High-potency topical steroids can be applied under occlusion in acute or severe disease. High-dose pulse corticosteroid therapy is effective in acute alopecia areata but is not useful in ophiasis or long-standing alopecia totalis/universalis. Topical immunotherapy with diphenylcyclopropenone (DPCP) or squaric acid dibutylester (SADBE), which is not approved by the U.S. Food and Drug Administration (FDA), is an effective option in chronic alopecia areata. Oral Janus kinase inhibitors (e.g., baricitinib, 2 to 4 mg daily;[A5] ruxolitinib, 10 to 20 mg twice daily; tofacitinib, 5 to 10 mg twice daily; and ritlecitinib, optimal dose still not established)[A6] have been highly effective in inducing hair regrowth in severe alopecia areata,[11] although relapses often occur if drug treatment is interrupted. Baricitinib is FDA-approved for the treatment of severe alopecia areata, and two other JAK inhibitors (ritlecitinib and deuruxolitinib) are presently being reviewed for approval.

TRICHOTILLOMANIA

Trichotillomania is a compulsive disorder that is more common in children. Repetitive hair pulling and plucking produces patches of irregular alopecia. The scalp is not completely bald, but rather shows broken hairs of various lengths (Fig. 409-3). The frontal, parietal, and occipital scalp are most commonly affected, but other terminal hairs can be involved, especially the upper eyelashes.

Occasionally, patients develop the habit of chewing or eating the pulled hairs. Patients with trichotillomania frequently do not admit their habit, and parents of affected children may be recalcitrant to accept the diagnosis. Psychiatric referral is indicated in adults.

FIGURE 409-1. Alopecia areata: patchy hair loss. The alopecic area is devoid of hairs, and the scalp does not present inflammatory changes. Note diffuse thinning of the scalp surrounding the patch.

FIGURE 409-2. Alopecia areata: patchy hair loss. Hair loss involves the eyelashes and eyebrows.

CICATRICIAL ALOPECIAS (SCARRING ALOPECIA)

The hallmark of cicatricial alopecias is loss of follicular ostia. Cicatricial alopecias include diseases that primarily affect the hair follicles and diseases that affect the dermis and secondarily cause follicular destruction.

Primary cicatricial alopecias are classified as lymphocytic or neutrophilic, based on the principal inflammatory cell type seen on pathologic examination. Lymphocytic cicatricial alopecias include lichen planopilaris, frontal fibrosing alopecia, and discoid lupus erythematosus. Neutrophilic cicatricial alopecias include folliculitis decalvans and dissecting cellulitis.

Secondary cicatricial alopecias result from disorders that cause diffuse scarring of the dermis, including burns, radiation, severe skin infections, localized scleroderma, and scalp tumors. The diagnosis of primary scarring alopecia requires a scalp biopsy, which should be taken from areas with active evidence of inflammation because biopsy of atrophic scalp will typically show only follicular or dermal fibrosis. In scarring alopecias, hair loss is permanent; treatment can prevent progression but not induce hair regrowth.

LICHEN PLANOPILARIS/FRONTAL FIBROSING ALOPECIA

In lichen planopilaris, which is the most common form of cicatricial alopecia, the hair follicles surrounding the alopecic patches show perifollicular erythema and scaling. The patient usually complains of severe itching. A variant of lichen planopilaris is frontal fibrosing alopecia, which typically affects postmenopausal women, in which it causes recession of the frontotemporal hairline, often associated with loss of the eyebrows and hairs of the

FIGURE 409-3. Trichotillomania: patchy hair loss. Irregular areas of alopecia with hairs broken at different lengths.

arms and legs (Fig. 409-4). Frontal fibrosing alopecia is becoming increasingly common worldwide.[12] No therapy is consistently effective, but retrospective studies indicate that 5α-reductase inhibitors are effective in arresting disease progression in a high percentage of patients.

DISCOID LUPUS ERYTHEMATOSUS

In discoid lupus erythematosus, the alopecic area shows active inflammation with erythema, edema, scaling, and follicular plugging, as well as atrophy with variable degrees of telangiectasia and dyspigmentation (Fig. 409-5).

The disease is more common in African American women. Approximately 5 to 10% of adults with discoid lupus erythematosus will develop systemic lupus erythematosus (Chapter 245), especially those with widespread discoid lesions. In localized lesions, treatment with high-potency topical steroids (see Table 404-1 in Chapter 404) is usually effective. Antimalarials are a second-line treatment. Hair regrowth may occur when treatment is promptly started. Therapeutic strategy should include photoprotection of the involved area.

FOLLICULITIS DECALVANS

In folliculitis decalvans, the scalp shows papulopustular lesions that often coalesce to form exudative crusted areas that result in cicatricial alopecia. A typical finding is tufted folliculitis, in which tufts of 6 to 15 hairs emerge together from the scalp (Fig. 409-6). The cause is unknown, but the condition may reflect an abnormal host response to bacterial antigens. *Staphylococcus aureus* often is isolated from active lesions. Folliculitis decalvans responds to oral antibiotics (e.g., trimethoprim-sulfamethoxazole [one tablet, 160 mg/800 mg/day] or clindamycin [300 mg twice daily] with or without rifampin [300 mg twice daily] for 8 to 10 weeks) but usually relapses after interruption of therapy.

DISSECTING CELLULITIS

Dissecting cellulitis of the scalp is a follicular occlusion disorder that may progress to scarring alopecia. Patients typically complain of relapsing multifocal alopecic painful nodules, boggy plaques, and draining tracts. Possible treatments include systemic antibiotics, isotretinoin, and tumor necrosis factor–α inhibitors, but data are limited to small case series.

HAIR DISORDERS IN CHILDREN

Hereditary and congenital alopecias are present since birth or appear in the first years of life. Aplasia cutis congenita is the most common form of focal alopecia in newborns.

Hereditary hair shaft abnormalities associated with increased hair fragility produce diffuse or patchy alopecia that appears during childhood. The most common hereditary hair shaft disorder is monilethrix, in which hair

FIGURE 409-4. Alopecia. A, Frontal fibrosing alopecia. Scarring alopecia of the hair margin with recession of the frontal hairline. The alopecic area can be easily distinguished because it shows no photoaging compared with the normal forehead. **B,** Note alopecia of the eyebrows and facial papules.

FIGURE 409-5. Discoid lupus erythematosus. The alopecic patch shows erythema, scaling, and depigmentation.

shaft fragility is associated with follicular hyperkeratosis. The hair is dull and fragile and breaks easily, especially in the nape and occipital areas. Diagnosis is confirmed by finding hair beading on dermoscopy or microscopic examination.

Congenital triangular alopecia is usually noticed by the age of 6 years as an irregularly triangular patch of alopecia with vellus hairs on the frontotemporal region.

The loose anagen hair syndrome is characterized by a defective anchorage of the hair to the follicle, resulting in hairs that are easily and painlessly pulled out from the scalp. The condition is typical of children and may manifest with patchy hair loss due to hair pulling while playing.

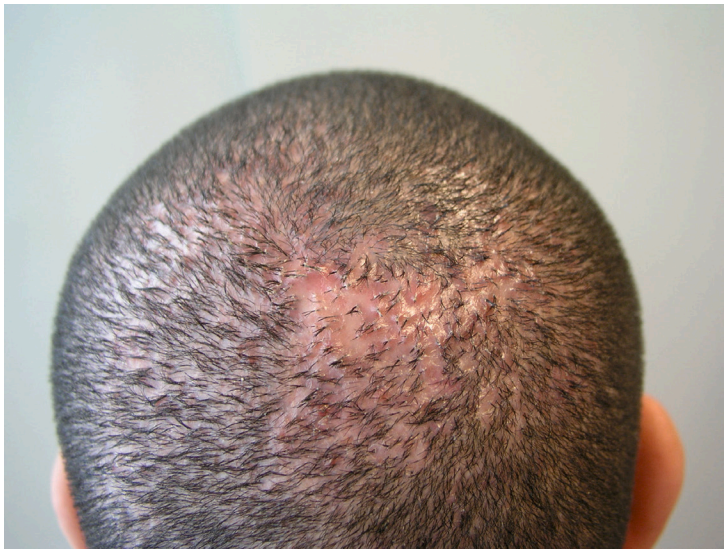

FIGURE 409-6. Folliculitis decalvans. Scarring alopecia with tufted folliculitis.

FIGURE 409-8. Central centrifugal cicatricial alopecia. The alopecic area involves the central portion of the scalp and expands centrifugally.

FIGURE 409-7. Traction alopecia. Hair loss involves the temporal scalp. Note presence of remaining hairs along the hairline (fringe sign).

Short anagen syndrome is a congenital disease characterized by short (<6 cm) fine hair and increased hair shedding. The condition is due to a decreased duration of the anagen phase.

RACIAL DIFFERENCES

The frequency and clinical aspects of hair disorders vary in different races. Androgenetic alopecia, for instance, is more frequent in Whites than in Blacks and Asians, whereas Black and Asian hair is more susceptible to weathering and fragility.

The Black hair shaft is flat, highly twisted, and difficult to manage without strong chemical or hair styling procedures, which often cause considerable damage. Hair straightening and braiding are responsible for traction alopecia, which is common and typically produces cicatricial alopecia of the frontal and lateral margins (Fig. 409-7). Central centrifugal cicatricial alopecia is a very common cause of scarring alopecia in Black women (Fig. 409-8). It manifests as slowly progressive scarring hair loss in the vertex or crown that spreads in a centrifugal pattern.[13]

In Asians, the hair shaft is round, thick, robust, and straight. Asian hair is very difficult to style and dye, and it is often damaged by its treatment with high concentrations or long exposure to chemicals.

EXCESSIVE HAIR GROWTH

Hirsutism describes excessive terminal hair with male distribution in a female. Hirsutism should be distinguished from hypertrichosis, which is characterized by the presence of an excessive amount of hair in a non–androgen-dependent area.

HIRSUTISM

Hirsutism is a common condition that affects up to about 8% of women[14] and is more frequent in Hispanic and Mediterranean women. Hirsutism may be associated with hyperandrogenism and polycystic ovary syndrome (Chapters 217 and 218), but it is idiopathic in approximately 15% of cases. Effective treatments include oral contraceptive agents, flutamide (62.5 to 500 mg/day), and spironolactone (100 mg daily) for severe cases.[A7]

HYPERTRICHOSIS

Hypertrichosis results from the presence of terminal hairs in anatomic areas that are normally characterized by vellus hair. Hypertrichoses can be congenital or acquired, localized or generalized. Acquired hypertrichoses are most commonly iatrogenic, metabolic (e.g., Cushing syndrome, porphyria, hyperthyroidism), nutritional (e.g., anorexia nervosa), or paraneoplastic (Chapter 164).

NAIL DISORDERS

Normal Nail

The nail plate is a keratinized hard structure produced by the nail matrix, which is a specialized epithelium located above the distal phalanx of the finger. In longitudinal sections, the matrix consists of a dorsal, an apical, and a ventral portion. The proximal matrix (dorsal portion and apex) produces the dorsal nail plate (two thirds upper plate), and the distal matrix (ventral portion) produces the ventral plate (one third lower plate). The nail plate is produced continuously throughout life. Nails grow slowly, and the nail plate can reflect illnesses that occurred several months earlier. Complete replacement takes approximately 6 months for fingernails and 12 to 18 months for toenails. Many medications (e.g., anticonvulsants, neuroleptics, antifungals), drugs (e.g., amphetamine, cocaine, doping substances), and poisons (e.g., mercury, arsenic) are retained in the nails, whose fragments (nail clippings) can be used to monitor previous exposure.

Nail abnormalities can be congenital or acquired and may be caused by developmental, traumatic, inflammatory, infective, and neoplastic disorders or by medications.[15,16] The diagnosis of nail dystrophies usually relies on a careful clinical examination and an accurate history, but radiographic or magnetic resonance imaging investigation of the digit and pathology may be required to guide treatment.[17]

KOILONYCHIA (SPOON NAILS)

In koilonychias (Fig. 409-9), which is also called spooning of the nails, the nail plate is thin and has a concave appearance. Koilonychia is physiologic in children. In adults, it can be occupational or, more rarely, a sign of iron deficiency (Chapter 145).

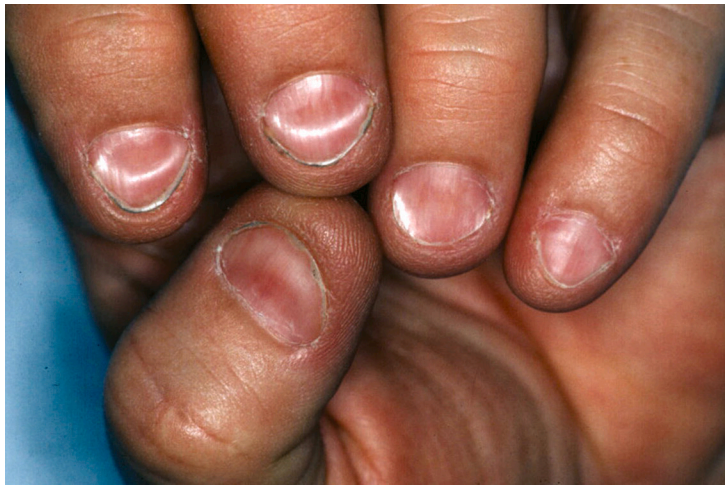

FIGURE 409-9. Spooning.

FIGURE 409-10. Clubbing.

CLUBBING

Clubbing (Fig. 409-10) develops when enlargement of the soft tissue of the distal digit causes a bulbous digit with an enlarged and overcurved nail plate. The angle between the proximal nail fold and the nail plate (Lovibond angle) is greater than 180 degrees. Clubbing may be congenital (i.e., in congenital heart disease; Chapter 55) or acquired. Other causes of acquired clubbing include intrathoracic (Chapter 177) and gastrointestinal neoplasms (Chapters 178 to 181), chronic intrathoracic suppurative disease (Chapter 78), inflammatory bowel disease (Chapter 127), and liver disorders.[18]

BEAU LINES AND ONYCHOMADESIS

Beau lines (Fig. 409-11) and onychomadesis are due to a temporary reduction or arrest of nail growth. Beau lines appear as transverse grooves of various depth; onychomadesis as a full-thickness transverse groove of the proximal nail plate. Causes include trauma, skin diseases involving the proximal nail fold and the matrix, drugs, and systemic diseases (Table 409-4), as well as SARS-CoV-2 infection, which can also cause a "red half moon sign" characterized by an erythematous half moon–shaped band surrounding the distal margin of the lunula (Table 409-5).[19] In systemic disease, Beau lines or onychomadesis involve all the nails and are localized at the same level.

PITTING

Pitting (Fig. 409-12) appears as punctate depressions of the dorsal nail plate, with variable size and depth. Pitting is caused by inflammatory skin disorders such as psoriasis (Chapter 405), alopecia areata, and eczema (Chapter 405).

FIGURE 409-11. Beau lines due to chemotherapy. The lines affect all the nails at the same level.

TABLE 409-4 CAUSES OF BEAU LINES AND ONYCHOMADESIS

SYSTEMIC
Acrodermatitis enteropathica
Severe metabolic stress
High fever
Viral infections (severe acute respiratory syndrome coronavirus 2, Kawasaki disease, measles, hand-foot-and-mouth syndrome)
Typhus
Stevens-Johnson syndrome
Drugs
Bullous disorders (pemphigus, pemphigoids)
Deep saturation, high altitude
Hemodialysis
Myocardial infarction
LOCAL
Trauma (including manicure)
Paronychia
Congenital malalignment (big toenails)

TABLE 409-5 NAIL SIGNS OF SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2 INFECTION

Chilblain-like lesions, most commonly on toenails (see Chapters 66 and 336)
Beau lines
Onychomadesis
Transverse true leukonychia (Mee lines)
Transverse orange discoloration
Red half-moon sign (erythematous band surrounding distal margin of the lunula)

LONGITUDINAL GROOVES AND STRIATIONS

Normal nails often show superficial thin longitudinal ridges that increase in number with aging. Deep longitudinal fissures, which indicate damage to the proximal matrix, can be caused by nail lichen planus, vascular insufficiency, trauma, and tumors involving or compressing the matrix.

LEUKONYCHIA

Leukonychia describes a whitish discoloration of the nail, which may be due to persistence of nuclei in the cells of the ventral nail plate (true leukonychia) or to a pallor of the nail bed (apparent leukonychia). True leukonychia, including the Mees lines of arsenic exposure (Chapter 20), does not fade with pressure and moves distally with nail growth; it is most commonly caused by trauma.

FIGURE 409-12. Pitting. Multiple punctate depressions on the nail plate surface.

FIGURE 409-13. Muehrcke lines. Note two parallel lines of apparent leukonychia.

Apparent leukonychia, which does not follow nail growth and fades with pressure, may be a sign of systemic diseases such as liver cirrhosis (Terry nails; Chapter 132), chronic renal diseases (half-and-half nails, characterized by apparent leukonychia of the proximal half of the nail; Chapter 116), hypoalbuminemia (Chapter 107), and systemic chemotherapy (Muehrcke lines; Fig. 409-13).

YELLOW NAIL SYNDROME

The yellow nail syndrome is a chronic nail disorder characterized by an arrest or a reduction of nail growth, resulting in nail thickening and hardening and yellow discoloration. Fingernails and toenails are excessively curved from side to side, and cuticles are absent (Fig. 409-14). Yellow nail syndrome occasionally may be paraneoplastic (Chapter 164). The pathogenesis of yellow nail syndrome is unknown, but a congenital abnormality of the lymphatic vessels may be involved.[20] Typical cases have associated lymphedema or respiratory disturbances. The nail abnormalities improve with treatment of the associated respiratory disorders. Oral vitamin E (1200 mg/day for several months) is useful in some cases.

SPLINTER HEMORRHAGES

Splinter hemorrhages (see Fig. 39-10 in Chapter 39) appear as longitudinal thin red-brown lines of variable length. Splinter hemorrhages are usually localized in the distal nail and are commonly seen in inflammatory diseases, including eczema (Chapter 405), psoriasis (Chapter 405), and onychomycosis (Table 409-6). Multiple splinter hemorrhages localized in the proximal nail plate can be a sign of systemic diseases, including infectious or marantic endocarditis (Chapter 61), trichinosis (Chapter 327), and the antiphospholipid syndrome.

FIGURE 409-14. Yellow nail syndrome. The nails are yellow, are overcurved, and do not grow.

TABLE 409-6 CONDITIONS ASSOCIATED WITH SPLINTER HEMORRHAGE

DERMATOSIS
Psoriasis

ONYCHOLYSIS

Onycholysis (Fig. 409-15) describes detachment of the nail plate from the bed. The detachment usually occurs at the free lateral margins of the nail. The onycholytic area is white owing to the presence of air, but it may acquire a green-brown color if the space is colonized by bacteria, such as *Pseudomonas aeruginosa*.

Onycholysis of the fingernails is a common sign of nail psoriasis (Chapter 405). It also may be due to prolonged and frequent contact with water, detergents, or irritants (idiopathic onycholysis). Toenail onycholysis is almost exclusively caused by trauma or onychomycosis. When onycholysis is limited to one digit, the possibility of a nail tumor always should be considered.

PARONYCHIA

Paronychia, which describes the acute or chronic inflammation of the proximal and lateral nail folds, is common in the fingernails at any age. In acute paronychia, the affected digit is painful, with erythema, swelling, and pus

FIGURE 409-15. Onycholysis. The detached nail plate is white in color.

discharge localized to one corner of the proximal nail fold. Acute paronychia usually follows a trauma to the nail fold, as in children who pick or bite the cuticles or in women after a manicure.

In chronic paronychia, prolonged mechanical or environmental trauma (such as contact with water and irritants) damages the cuticle, allowing penetration of dirt, bacteria, and other particles under the proximal nail fold. The result is an inflammatory reaction of the proximal nail fold and nail matrix, with edema and redness of the fold, absence of the cuticles, Beau lines, and abnormalities of the nail plate surface. Treatment includes protective measures, such as use of cotton and rubber gloves to avoid contact with irritants, as well as topical steroids and topical antimicrobials. Acute paronychia, often associated with periungual pyogenic granuloma-like lesions, is a common side effect of treatment with epidermal growth factor receptor (EGFR) inhibitors.

ONYCHOMYCOSIS

Fungal nail infections most commonly affect the toenails of adults. Dermatophytes (particularly *Trichophyton rubrum*) are responsible for most infections. The clinical presentation varies depending on the modality of the nail invasion. In distal subungual onychomycosis, the most common form, fungi spread from plantar skin and invade the nail bed. The affected nail shows subungual hyperkeratosis, onycholysis, and yellow streaks (Fig. 409-16). In white superficial onychomycosis, which only affects toenails, fungi colonize the surface of the nail plate, where they cause multiple white friable patches (Fig. 409-17). Proximal subungual onychomycosis produces a true leukonychia, owing to the presence of fungal hyphae in the deep layers of the plate. Proximal subungual onychomycosis caused by *T. rubrum* is typical in immunosuppressed patients. Diagnosis of onychomycosis must always be confirmed by mycologic examination.

TREATMENT

Treatment depends on clinical type, number of affected nails, and severity of nail involvement.[21] A systemic treatment is preferred for proximal subungual onychomycosis and for distal subungual onychomycosis involving the proximal nail. Terbinafine (250 mg/day) for 2 months (fingernails) or 3 months (toenails) is the most effective treatment for dermatophyte infections.[A8] Topical efinaconazole[A9,A10] and tavaborole,[A11] usually used daily for 6 months, are FDA approved for mild/moderate onychomycosis of the toenails, but these antifungal medications are not as effective as oral terbinafine.

INGROWING TOENAILS

Ingrown toenails are a common condition, especially in young patients. Nail ingrowing most commonly affects one or both the big toes and is related to

FIGURE 409-16. Distal subungual onychomycosis. The nail shows subungual hyperkeratosis and a yellow streak.

FIGURE 409-17. White superficial onychomycosis. The affected nail shows white superficial patches.

genetic factors, hyperhidrosis, and poorly fitting shoes. Ingrowing is usually precipitated by incorrect nail trimming, with formation of a sharp edge (spicule) of the lateral nail plate that penetrates and injures the soft tissues of the lateral nail fold (Fig. 409-18). Depending on severity, treatment varies from simple disembedding of the spicule to chemical destruction of the lateral nail matrix by phenolization.

NAIL PIGMENTATION

Nail pigmentation is usually caused by staining from external agents, such as nicotine or hair dyes. It rarely may be due to drug deposition in the nail plate or into the nail bed (i.e., antimalarials) or systemic diseases (argyria). In these cases, the proximal margin of the pigmentation follows the shape of the lunula.

MELANONYCHIA

Melanonychia is defined by the presence of melanin within the nail plate. It appears more often as a longitudinal brown-black band starting from the matrix and extending to the free edge of the nail plate (Fig. 409-19).

Melanonychia results from production of melanin by melanocytes of the nail matrix. Melanonychia has three main causes: simple melanocytic activation, benign melanocyte proliferations (lentigo, nevus), and malignant melanocyte proliferation (melanoma; Chapter 188).

Common causes of longitudinal melanonychia due to melanocytic activation include inflammatory and traumatic nail disorders, drugs (chemotherapy,

FIGURE 409-18. Ingrowing toenail. Penetration of the nail spicule causes inflammation and granulomatous reaction.

FIGURE 409-20. Nail melanoma. Melanonychia and periungual pigmentation (Hutchinson sign).

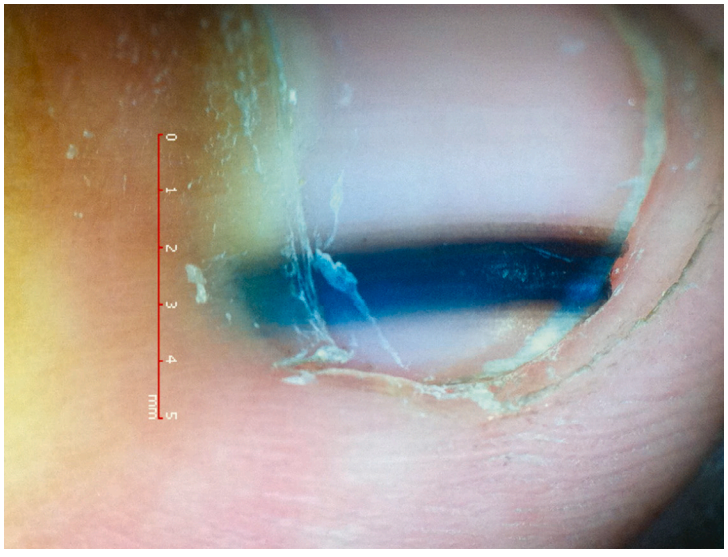

FIGURE 409-19. Longitudinal melanonychia. Black longitudinal pigmented band extending from the proximal nail fold to the free edge.

azidothymidine, antimalarials, or psoralen and ultraviolet A [PUVA] therapy), and systemic diseases (acquired immunodeficiency syndrome [Chapter 359]; Addison disease [Chapter 208]).

Nail melanoma is rare and most frequently involves the thumb of middle-aged individuals. Diagnosis is often delayed, and the 5-year survival rate is only 15%. Hutchinson sign, extension of the pigmentation to the proximal or lateral nail folds, is an important indicator of nail melanoma (Fig. 409-20).

APPENDIX

REFERENCE INTERVALS AND LABORATORY VALUES

JORGE SEPULVEDA

This Appendix contains tables of reference values for common laboratory tests used in the practice of internal medicine. This information can provide important guidelines for the clinician but should not be used as absolute indicators of health and disease. For essentially every test, significant overlap exists between healthy and diseased populations.

A variety of factors can influence reference values. Such variables include the population studied, the duration and means of specimen transport, laboratory methods and instrumentation, and even the type of container used for the collection of the specimen. The reference or "normal" ranges given in this Appendix may therefore not be appropriate for all laboratories, and these values should only be used as general guidelines. Whenever possible, the reference values provided by the laboratory performing the testing should be utilized in the interpretation of laboratory data.

Values supplied in this Appendix reflect typical reference ranges in nonpregnant adults.[1] Values for older adults (e.g., >60 years old) and other age groups are provided when relevant. Pediatric reference ranges and values in pregnant patients may vary significantly from the data presented in the Appendix. Pediatric reference ranges can be obtained from the Canadian Laboratory Initiative on Pediatric Reference Intervals (CALIPER) study.[2]

In preparing the Appendix, the author has taken into account the fact that the system of international units (SI, système international d'unités) is used in most countries and in some medical journals. However, clinical laboratories may continue to report values in "traditional" or conventional units. Therefore, both systems are provided in the Appendix. If the value and units for a reference interval are the same for conventional and international units, the interval is listed only in the column for international units. The dual system is also used in the text except for those instances in which the numbers remain the same and only the terminology is changed (mmol/L for mEq/L or IU/L for mIU/mL), when only the SI units are given. In some cases (e.g., cholesterol, triglycerides, glucose), guideline-based recommendations for desirable values or medical decision levels are provided instead of the reference range, which may vary markedly among populations and environmental settings.

TABLE APPENDIX-1 PREFIXES AND ABBREVIATIONS

PREFIXES DENOTING DECIMAL FACTORS

PREFIX	SYMBOL	FACTOR
mega	M	10^{6}
kilo	k	10^{3}
hecto	h	10^{2}
deca	da	10^{1}
deci	d	10^{-1}
centi	c	10^{-2}
milli	m	10^{-3}
micro	μ	10^{-6}
nano	n	10^{-9}
pico	p	10^{-12}
femto	f	10^{-15}

ABBREVIATIONS

ADA	American Diabetes Association
AU	Arbitrary units
CSF	Cerebrospinal fluid
DDU	D-dimer units
EDTA	Ethylenediaminetetraacetic acid
EU	Ehrlich unit
F	Female
Hb	Hemoglobin
hpf	High-power field
IFA	Immunofluorescent assay
IFCC	International Federation of Clinical Chemistry
IU	International unit (of hormone activity)
Kat	Katal
KDIGO	Kidney Disease Improving Global Outcomes
M	Male
Pa	Pascal
RBC	Red blood cell
RID	Radial immunodiffusion
S	Substrate
U	International unit (of enzyme activity)
WBC	White blood cell

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, AND SEROLOGY

			REFERENCE INTERVAL (CONVENTIONAL UNITS)			*REFERENCE INTERVAL (INTERNATIONAL UNITS)*		
TEST	**SPECIMEN**	**CONDITION**	***LOWER***	***UPPER***	***UNITS***	***LOWER***	***UPPER***	***UNITS***
Acetoacetate, semiquantitative	Serum or plasma		0.5	3.0	mg/dL	49	298	μmol/L
Acetone, quantitative	Serum or plasma	Undetected if < lower limit	0.5	100	mg/dL	0.09	17.2	μmol/L
	Urine	Toxic if ≥ upper limit	10	100	mg/dL	1.7	17.2	mmol/L
Adrenocorticotropic hormone (ACTH)	Plasma (EDTA)	Morning	7	63	pg/mL	1.5	13.5	pmol/L
Alanine aminotransferase (ALT, SGPT)	Serum or plasma		9	50	U/L	0.15	0.85	μKat/L
Albumin	Serum or plasma		3.9	5.2	g/dL	39	52	g/L
	CSF		0	35	mg/dL	0	350	mg/L
	Urine		0	29.9	mg/g creatinine	0.00	3.38	mg/mmol creatinine
Aldosterone	Serum or plasma	Adults, average sodium diet						
		Supine	0	16	ng/dL	0	0.44	nmol/L
		Upright	4	31	ng/dL	0.12	0.86	nmol/L

TABLE APPENDIX-2 CLINICAL CHEMISTRY, TOXICOLOGY, AND SEROLOGY—cont'd

			REFERENCE INTERVAL (CONVENTIONAL UNITS)			REFERENCE INTERVAL (INTERNATIONAL UNITS)		
TEST	**SPECIMEN**	**CONDITION**	***LOWER***	***UPPER***	***UNITS***	***LOWER***	***UPPER***	***UNITS***
Alkaline phosphatase, IFCC	Serum or plasma	M, F (>19 yr)	40	129	U/L	0.68	2.19	μKat/L
Aluminum	Serum, metal-free tube		0	15	μg/L	0	0.56	μmol/L
		On hemodialysis	0	55	μg/L	0	2.1	μmol/L

Pronormoblasts		1.0-8.0 (4.0)	0.01-0.08 (0.04)
Normoblasts		7.0-32.0 (18.0)	0.07-0.32 (0.18)
D-dimer	Plasma (Na citrate)	0.0-0.5 µg/mL DDU	0-500 µg/L DDU
Differential count (see bone marrow differential count or leukocyte differential count)			
Erythrocyte count (RBC count)	Whole blood (EDTA)	$\times 10^6$ cells/µL F: 3.8-5.1 M: 4.2-5.7	$\times 10^{12}$ cells/L 3.8-5.1 4.2-5.7
Erythrocyte sedimentation rate (ESR), Westergren	Whole blood (EDTA)		F: <50 y: 0-25 mm/hr >50 y: 0-30 mm/hr M: <50 y: 0-15 mm/hr >50 y: 0-20 mm/hr
Fibrin degradation products	Plasma (Na citrate)	0-1 µg/mL	0-1 mg/L
Fibrinogen	Plasma (Na citrate)	191-430 mg/dL	1.91-4.30 g/L
Glucose-6-phosphate dehydrogenase (G6PD) in erythrocytes	Whole blood (ACD, EDTA, or heparin)	≤39 minutes	≤2400
Hematocrit (HCT)	Whole blood (EDTA)	F: 33.8-43.3% M: 37.2-47.9%	0.34-0.43 volume fraction 0.37-0.48 volume fraction
Hemoglobin (Hb)	Whole blood (EDTA)	F: 11.2-14.7 g/dL M: 12.6-17.0 g/dL	112-147 g/L 126-170 g/L
Hemoglobin electrophoresis	Whole blood (EDTA, citrate, or heparin)	HbA: >95% HbA_2: 1.5-3.5% HbF: <2%	>0.95 0.015-0.035 <0.02
Immature platelet fraction (IPF)	Whole blood (EDTA)	F: 0.9-7.9% M: 1.3-8.2%	0.009-0.079 0.013-0.082
Immature reticulocyte fraction (IRF)		2.8-13.1%	0.028-0.131

TABLE APPENDIX-3 HEMATOLOGY AND COAGULATION—cont'd

TEST	SPECIMEN	REFERENCE INTERVAL (CONVENTIONAL UNITS)		REFERENCE INTERVAL (INTERNATIONAL UNITS)	
International normalized ratio (INR)	Plasma (Na citrate)	Relevant only in patients on warfarin $INR = \left[\frac{\text{Patient PT}}{\text{Normal mean PT}}\right]^{ISI}$ ISI = International sensitivity index of thromboplastin		INR 2.0-3.0 (for most indications)	
Leukocyte count (WBC count)	Whole blood (EDTA) CSF	F: 3.5-9.4 × 10^3 cells/μL M: 3.1-8.4 × 10^3 cells/μL 0.5 mononuclear cells/μL		3.5-9.4 × 10^9 cells/L 3.1-8.4 × 10^9 cells/L 0.5 × 10^6 cells/L	
Leukocyte Differential count:	Whole blood (EDTA)	*% cells*	*Cells (counts/μL)*	*Fraction of cells counted*	*Cells (×10^9/L)*
Neutrophils		43-75	1400-5800	0.43-0.75	1.4-5.8
Lymphocytes		17-45	950-3070	0.17-0.45	0.95-3.07
Monocytes		4.0-9.4	260-810	0.040-0.094	0.26-0.81
Eosinophils		0.2-4.9	30-480	0.002-0.049	0.03-0.48
Basophils		0.2-1.6	10-80	0.002-0.016	0.01-0.08
Immature granulocytes		0-0.5	0-30	0-0.005	0-0.03
Nucleated red blood cells		0	0	0	0
Leukocyte Differential count	CSF	*% cells*		*Number fraction*	
Lymphocytes		62 ± 34		0.62 ± 0.34	
Monocytes (includes pia-arachnoid mesothelial cells)		36 ± 20		0.36 ± 0.20	
Neutrophils		2 ± 5		0.02 ± 0.05	
Histiocytes				Rare	
Ependymal cells				Rare	
Eosinophils				Rare	
Mean corpuscular hemoglobin (MCH)	Whole blood (EDTA)	F: 26-33 pg/cell M: 27-33 pg/cell		0.26-0.33 fmol/cell 0.27-0.33 fmol/cell	
Mean corpuscular hemoglobin concentration (MCHC)	Whole blood (EDTA)	31-37% Hb/cell or g Hb/dL RBC		4.81-5.74 mmol Hb/L RBC	
Mean corpuscular volume (MCV)	Whole blood (EDTA)			F: 78.6-94.2 fL M: 79.4-94.7 fL	
Mean platelet volume (MPV)	Whole blood (EDTA)			F: 8.7-12.5 fL M: 9.0-12.1 fL	
Plasma volume	Whole blood (heparin)	F: 28-45 mL/kg M: 25-43 mL/kg		0.028-0.045 L/kg 0.025-0.043 L/kg	
Platelet count (thrombocyte count)	Whole blood (EDTA)	167-374 × 10^3/μL (μL) 159-325 × 10^3/μL (μL)		167-374 × 10^9/L 159-325 × 10^9/L	
Prothrombin time, one-stage	Plasma (Na citrate)	Reference values will vary with the type of thromboplastin		In general: 11-16 sec	
Red cell volume	Whole blood (heparin)	F: 19-31 mL/kg M: 20-36 mL/kg		0.019-0.031 L/kg 0.020-0.036 L/kg	
Red cell distribution width, coefficient of variation (RDW-CV)	Whole blood (heparin)	F: 11.4 14.7% M: 11.3 13.9%		0.114-0.147 0.113-0.139	
Reticulocyte count	Whole blood (EDTA, heparin, or oxalate)	0.77-2.26% of erythrocytes		0.0077-0.0226 (number fraction)	
Reticulocyte count, absolute	Whole blood (EDTA, heparin, or oxalate)	25,000-100,000/μL		25-100 × 10^9/L	
Reticulocyte hemoglobin	Whole blood (EDTA, heparin, or oxalate)			F: 29.2-37.8 pg M: 31.2-38.8 pg	
Thrombin time	Plasma (Na citrate)	15.0-18.9 seconds		15.0-18.9 seconds	
von Willebrand factor activity	Plasma (Na citrate)	51-215%		0.51-2.15 activity ratio	
von Willebrand factor antigen	Plasma (Na citrate)	52-214%		0.52-2.14 activity ratio	

ACD = acid citric dextrose; CSF = cerebrospinal fluid; EDTA = ethylenediaminetetraacetic acid; F = female; M = male; PT = prothrombin time; RBC = red blood count; WBC = white blood count.

TABLE APPENDIX-4 DRUGS: THERAPEUTIC AND TOXIC

			CONVENTIONAL UNITS				INTERNATIONAL UNITS			
			THERAPEUTIC RANGE				THERAPEUTIC RANGE			
DRUG	SPECIMEN	CONDITION	LOW	HIGH	TOXIC if >	UNITS	LOW	HIGH	TOXIC if >	UNITS
Acetaminophen	S/P	4-6 hr after dose	10	30	150	µg/mL	66	199	993	µmol/L
Amikacin	S/P	Peak	20	25	35	µg/mL	34	43	60	µmol/L
		Peak, urinary tract infection and gram-negative infections	25	30	35	µg/mL	45	51	60	µmol/L
		Trough	5	10	10	µg/mL	9	17	17	µmol/L
Amiodarone	S/P		0.5	2.0	2.5	µg/mL	0.7	2.9	3.7	µmol/L
Amitriptyline + nortriptyline	S/P		95	250	500	ng/mL	343	903	1805	nmol/L
Caffeine	S/P		8	20	20	µg/mL	41	103	103	µmol/L
Carbamazepine	S/P		4	12	15	µg/mL	17	51	64	µmol/L
Chloramphenicol	S/P		10	20	25	µg/mL	31	62	77	µmol/L
Chlorpromazine	S/P		30	300	750	ng/mL	94	942	2355	nmol/L
Cyclosporine A	WB	Trough (12 hr after dose)	25	525	700	ng/mL	21	436	581	nmol/L
Diazepam + nordiazepam	S/P		200	2500	3000	ng/mL	0.70	8.78	10.53	µmol/L
Digitoxin	S/P	8-12 hr after dose	10	30	45	ng/mL	13	39	59	nmol/L
Digoxin	S/P	>6 hr after dose	0.8	2.0	2.4	ng/mL	1.0	2.6	3.1	nmol/L
Diphenylhydantoin (see Phenytoin)										
Disopyramide	S/P		2.0	5.0	5.0	µg/mL	5.9	14.8	14.8	µmol/L
Doxepin + nordoxepin	S/P		100	300	500	ng/mL	358	1074	1790	nmol/L
Ephedrine	S/P		35	80	200	ng/mL	0.2	0.5	1.2	µmol/L
Ethanol	S/P	Impairment,			50	mg/mL	11	22		mmol/L
		CNS depression			100	mg/mL			22	mmol/L
		Life-threatening			400	mg/mL			87	mmol/L
Ethosuximide	S/P		40	100	150	µg/mL	283	708	1062	µmol/L
Everolimus	WB		3	8	15	ng/mL	3.0	8.6	16	nmol/L
Flecainide	S/P		0.2	1.0	1.0	µg/mL	0.5	2.0	2.0	µmol/L
Gabapentin	S/P		2	20	25	µg/mL	12.0	117	70	µmol/L
Gentamicin	S/P	Peak	5	10	12	µg/mL	10	21	25	µmol/L
		Trough	0.5	2	2	µg/mL	1	4	4	µmol/L
Haloperidol	S/P		5	17	42	ng/mL	13	45	112	nmol/L
Imatinib	P	GIST or CML	1000	1999	3200	ng/mL	2028	4054	6491	mmol/L
Imipramine + Desipramine	S/P		150	300	400	ng/mL	536	1071	1428	nmol/L
Itraconazole + hydroxyitraconazole	S/P		1.5		10	µg/mL	2		13	µmol/L
Lamotrigine	S/P		2.5	15		µg/mL	9.8	59		µmol/L
Levetiracetam	S/P		12	46		µg/dL	71	270		µmol/L
Lidocaine	S/P	>45 min post-bolus dose	1.2	5.0	9.0	µg/mL	5	21	38	µmol/L
Lithium	S/P	Trough (12 hr post dose)	0.5	1.2	1.6	mEq/L	0.5	1.2	1.6	mmol/L
Methotrexate	S/P	Low dose					0.5	1.0	1.0	µmol/L
		High dose (24 hr post)						5.0	5.0	µmol/L
		High dose (48 hr post)						0.5	0.5	µmol/L
		High dose (72 hr post)						0.1	0.1	µmol/L
Morphine	S/P		10	80	200	ng/mL	35	280	700	nmol/L
Mycophenolate	S/P		1.0	3.5	25	µg/mL	3.1	10.9	78	µmol/L
Nicotine	S/P	Use of or exposure to tobacco/ nicotine products	2.0	10.0		ng/mL	12	62		µmol/L
	Ur		17	700		ng/mL	105	4312		µmol/L

TABLE APPENDIX-4 DRUGS: THERAPEUTIC AND TOXIC—cont'd

			CONVENTIONAL UNITS				INTERNATIONAL UNITS			
			THERAPEUTIC RANGE				THERAPEUTIC RANGE			
DRUG	SPECIMEN	CONDITION	LOW	HIGH	TOXIC if >	UNITS	LOW	HIGH	TOXIC if >	UNITS
Nicotine metabolite (Cotinine)	S/P Ur		8 20	145 8000		ng/mL ng/mL	45 114	824 45440		µmol/L µmol/L
Oxcarbazepine	S/P		3	35	40	µg/mL	12	139	159	µmol/L
Paroxetine	S/P		30	120	120	ng/mL	91	365	365	nmol/L
Perphenazine	S/P	Low dose High dose	0.6 5	2.4 30	50 50	ng/mL ng/mL	2 17	6 75	125 125	µmol/L µmol/L
Phenobarbital	S/P		15	40	50	µg/mL	65	173	216	µmol/L
Phenytoin, total	S/P		10	20	30	µg/mL	40	79	119	µmol/L
Phenytoin, free	S/P		1.0	2.5	2.5	µg/mL	4.0	9.9	9.9	µmol/L
Primidone + phenobarbital	S/P		5	12	15	µg/mL	23	55	69	µmol/L
Procainamide	S/P		4	10	12.1	µg/mL	17	42	51	µmol/L
Procainamide + N-Acetyl (NAPA)	S/P		6	20	35.1	µg/mL	22	72	127	µmol/L
Propranolol	S/P		10	150		ng/mL	39	579		nmol/L
Protriptyline	S/P		70	260	500	ng/mL	266	988	1900	nmol/L
Quinidine	S/P		2	5	6	µg/mL	6	14	19	µmol/L
Salicylates	S/P		20	290	300	µg/mL	145	2103	2175	µmol/L
Sertraline	S/P		30	200	300	ng/mL	98	654	981	nmol/L
Sirolimus (Rapamycin)	WB		4	14	20	ng/mL	4	15	22	nmol/L
Tacrolimus	WB		5	25	25	ng/mL	6	30	30	nmol/L
Theophylline	S/P		8	20	20	µg/mL	44	111	111	µmol/L
Tobramycin	S/P	Peak Trough	5 0	10 2	10 2	µg/mL µg/mL	11 0	21 4	21 4	µmol/L µmol/L
Valproic acid	S/P		50	100	150	µg/mL	347	693	1040	µmol/L
Vancomycin	S/P	Combination therapy Aggressive therapy	10 15	15 20	28 28	µg/mL µg/mL	7 10	10 14	19 19	µmol/L µmol/L
Voriconazole	S/P		1.0	5.5	6.0	µg/mL	2.9	15.7	17.1	µmol/L
Warfarin	S/P		1.0	10	10	µg/mL	3	32	32	µmol/L
Zonisamide	S/P		10	40	80	µg/mL	47	188	376	µmol/L

CNS = central nervous system; CML = chronic myelogenous leukemia; GIST = gastrointestinal stromal tumor; S/P = serum or plasma; Ur = urine; WB = whole blood.

Anti-C5, 203
Anti-CD20 antibodies, 2701
Anti-citrullinated peptide antibodies (ACPA), 1750
Anti-cyclic citrullinated peptide antibody, 1707
Anti-endothelial cell antibodies, vasculitides and, 1794
Anti-epidermal growth factor antibodies, for colorectal cancer, 1350*b*
Anti-glomerular basement membrane (anti-GBM) disease, 784, 784*b*–785*b*, 784*f*, 784*t*, 1798
Anti-HER2 therapy, for breast cancer, 1369*b*
Anti-HMGCR myopathy, 1787–1789
Anti-IgA, 1202
Anti-IL2R monoclonal antibodies, in renal transplantation, 845*t*
Anti-infective therapy, principles of, 1840–1845. *See also* Antimicrobial therapy
Anti-inflammatory agents
  for acute STEMI, 384*b*
  for COVID-19, 2217
  for cystic fibrosis, 558*b*
  for radiation enteritis, 940*b*–941*b*
  for skin diseases, 2697–2699
Anti-ischemic therapies, for acute STEMI, 384*b*
Anti-La antibodies, 1715
Anti-La/SSB antibodies, in Sjögren syndrome, 1784
Anti-Parkinsonism medications, for Parkinson disease, 2486*b*
Anti-RNP antibodies, 1714
Anti-Ro antibodies, 1715
Anti-Ro/SSA antibodies, in Sjögren syndrome, 1784
Anti-*Saccharomyces cerevisiae* antibodies (ASCA), 945
Anti-Sm antibodies, 1714
Anti-tubular basement membrane disease, 790
Anti-tumor necrosis factor-α agents, for inflammatory bowel disease, 945*b*
Anti-vascular endothelial growth factor antibodies, for colorectal cancer, 1350*b*
Antianginal therapy, 374*t*
Antiarrhythmic drugs, 313*b*, 325*t*, 338*b*
  for acute STEMI, 384*b*
Antibacterial activity, synergism in, 1843–1844
Antibacterial chemotherapy, 1891–1902
  antibiotic selection, 1891–1892
  bacterial burden, 1893
  correct drug dose of, 1892
  culture, 1892
  dosages, 1891
  drug, classes and properties of, 1898–1900
  duration of therapy, 1900
  failure of, 1900–1902
  Gram stain, 1892
  infection site and, 1892, 1892*t*
  infection susceptibility to, 1892
  mechanism of action, 1894, 1895*t*
  pharmacokinetic of, changes of, 1894–1898, 1895*t*
  principles of, 1891
  resistance, 1892–1894, 1893*t*
  toxicities of, 1900, 1901*t*
Antibacterials, 1845*t*
  for skin diseases, 2699
Antibiotic(s)
  for acute bacterial prostatitis, 825*b*
  for acute bronchitis and tracheitis, 606*b*
  for acute mesenteric ischemia, 960*b*
  for asthma, 541*b*
  into cerebrospinal fluid, 2516*t*
  for common cold, 2193*b*
  for cystic fibrosis, 558*b*
  for diarrhea, 926*b*
  for diphtheria, 1935*b*
  for diverticulitis, 955*b*
  for *E. coli*, 1963*b*–1964*b*
  for esophagitis, 907*t*
  for inflammatory bowel disease, 945*b*
  for irritable bowel syndrome, 896*t*
  for malaria, 2121*b*
  for neutropenia, 1147*b*
  for perianal abscess, 979*b*
  for pyogenic liver abscess, 1023*b*
  reactions to, 1697–1698
  for relapsing fever, 2028*b*
  for shigellosis, 1981*b*–1982*b*
  for skin diseases, 2699
  for spondylitis, 1765*b*
  for *Stenotrophomonas maltophilia*, 1975*b*
  for *Streptococcus pneumoniae*, 1912*b*
  for viral hemorrhagic fevers, 2269*b*–2272*b*
Antibiotic-associated diarrhea, 926
Antibiotic resistance, mechanisms of, in Enterobacterales, 1965, 1966*t*
Antibodies, 152, 188, 192, 197
  for cancer, 1232*b*
  to citrullinated proteins, 1713
  monoclonal, for asthma, 541*b*
  specificities of, 188–189
Antibody deficiency, 1680–1682, 1681*t*
  clinical manifestations of, 1680–1682
  diagnosis of, 1682
  epidemiology and pathobiology of, 1680–1682, 1681*t*
  with normal immunoglobulins, 1682
  prognosis of, 1682
  treatment of, 1682*b*
Antibody-drug conjugates, 150*t*
Anticatabolic agents, for osteoporosis, 1643*b*
Anticholinergic agents
  central nervous system effects of, 685*t*
  toxidromes, 683*t*
Anticholinergic-antihistamine agents, for nausea and vomiting, 863*t*
Anticipatory anxiety, 2343
Anticoagulants, 364*b*, 501–506, 503*t*, 2666*t*, 2667*f*
  for giant cell arteritis, 1803*b*
  long-term use of, 487*b*–489*b*
  oral, 502*t*, 503–506
  parenteral, 501–503, 501*t*
  side effects of, 487*b*
Anticoagulation
  for acute coronary syndrome, 374*t*
  for acute STEMI, 384*b*, 387*f*
  for COVID-19, 2217
  in functional tests, 477–478
  for intracerebral hemorrhage, 2480*b*–2482*b*
  postoperative, 2667
  with warfarin, for portal vein thrombosis, 968*b*
Anticonvulsants
  central nervous system effects of, 685*t*
  for fibromyalgia, 1819*b*
  for myoclonus, 2493*b*–2494*b*
Antidepressants, 2679–2680, 2680*t*
  for anorexia nervosa, 1462*b*
  central nervous system effects of, 685*t*
  cyclic, toxicity, 686*t*
  in pregnancy, 1610
  tricyclic
    for chronic pain, 138*t*
    for depression, 2340*t*
    for fibromyalgia, 1819*b*
    screening for, 689*t*
Antidiarrheal agents, 940*b*, 941*b*
Antidiuresis, 1499
Antidiuretic hormone (ADH), *e*1*t*–*e*8*t*, 730–731, 738
Antidotes, for acute poisoning, 691*b*
Antidromic tachycardia, 323*t*, 326
Antiemetic regimens, for nausea and vomiting, 863*t*
Antiemetics, for intestinal pseudo-obstruction, 889*b*–890*b*
Antiepileptics, for alcohol withdrawal, 2358*t*
Antifibrinolytic agents, for disseminated intravascular coagulation, 1196*b*–1197*b*
Antifungal agents, 2074–2080, 2699
  amphotericin preparations as, 2077
  for aspergillosis, 2096
  azole, 2074–2077
    fluconazole as, 2075–2076
    indications and dosage of, 2075
    isavuconazole as, 2077
    itraconazole as, 2074–2075
    mechanisms of action, 2074
    posaconazole as, 2076–2077
    voriconazole as, 2076
  for coccidioidomycosis, 2085*b*
  dosing overview for, 2075*t*
  echinocandin, 2078–2079
    anidulafungin as, 2078
    caspofungin as, 2078
    mechanisms of action, 2078
    micafungin as, 2078
  flucytosine as, 2079
    adverse effects of, 2079
    drug interactions of, 2079
    formulation and pharmacology of, 2079
    indications and dosage of, 2075*t*, 2079
    mechanisms of action, 2079
  ibrexafungerp as, 2079
    adverse effects of, 2079
    drug interactions of, 2079
    indications and dosage of, 2075*t*, 2079
    mechanisms of action, 2079
  for mucormycosis, 2100*b*
  other, 2079
Antigen(s), 193*t*
  processing and presentation of, 188, 188*f*
  in transplantation, 203–205, 204*t*
Antigen-based testing, for COVID-19, 2214
Antigen detection, for malaria, 2120
Antigen-specific effector T cells, 193
Antigen-specific receptors, 188–189
Anti-glomerular basement membrane (anti-GBM), for glomerular syndromes, 727
Antihemophilic factor, 1189*t*
Antihistamines
  for acute bronchitis and tracheitis, 606*b*
  central nervous system effects of, 685*t*
  for rhinitis, 2632*b*–2634*b*
  for skin diseases, 2700, 2700*t*
Antihypertensive drugs, 1620*b*–1621*b*, 1621*t*
  classes of, 451–455
  interactions of, 455
  side effects of, 453*t*
  for specific condition, 454*t*
Antileukotrienes, 541*b*
Antimalarial drugs, 2698–2699
  for rheumatoid arthritis, 1755*b*–1758*b*
  for systemic lupus erythematosus, 1772*b*
Antimetabolites, for liver transplantation, 1048*t*
Antimicrobial resistance, 1834, 1965, 1966*t*
Antimicrobial therapy
  for *Acinetobacter* infection, 1974*b*
  administration of, 1844
  administrative aspects of, 1844–1845
  age and, 1843
  allergies to, 1842
  bactericidal activity of, 1842
  for bronchiectasis, 561*b*
  for *Campylobacter* infections, 1959*b*
  for cholera, 1956*b*–1957*b*
  combinations of, 1843
  definitive, 1841
  drug-drug interactions in, 1843
  drug resistance of, emergence of, 1843
  duration of, 1844
  empirical, 1840–1841
  failure of, 610*b*–611*b*, 1900
  for food poisoning, 1932*b*
  formularies for, 1844
  health care-associated infections and, 1863
  hepatic function in, 1843
  host factors, 1842–1844
  infection treated with, nature of, 1842
  pathogen of, identification of, 1841
  pharmacodynamic considerations in, 1844
  for plague, 1992*t*, 1993
  for pneumonia, 610*b*, 613*t*
  for polymicrobial infections, 1843
  in pregnancy, 1842–1843, 1842*t*
  renal function in, 1843
  resistance in, 1843
  route of administration, 1844
  selection of, 1840–1844
  for skin diseases, 2699
  stewardship for, 1844–1845, 1845*t*, 1865.*e*1*t*, 1867
  susceptibility testing of, 1836, 1840, 1916*b*
  toxicity of, 1843
Antimotility agents, for cholera, 1956*b*
Antimüllerian hormone, *e*1*t*–*e*8*t*, 1630
Antimuscarinics
  asthma and, 541*b*
  for benign prostatic hyperplasia, 822*b*
  for male lower urinary tract symptoms, 824*t*
Antineutrophil cytoplasmic antibodies (ANCA), 727, 1716, 1793–1794
Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, 965, 1707–1708
Antineutrophil cytoplasmic antibody-associated vasculitides, 1796–1798
Antinuclear antibodies (ANAs), 727, 1714–1716, 1714*f*, 1785
  in pulmonary hypertension, 495
  systemic sclerosis, 1780
Antioxidants, 196, 975*t*

Diethylcarbamazine (DEC), 2117–2118
for filariases, 2176*b*
for helminthic diseases, 2112*t*
for loiasis, 2179*b*–2180*b*
Dieulafoy lesion, 885*f*, 886, 918, 966, 967*f*
Dieulafoy ulcers, 913–914
Differential count, e8*t*–e9*t*
Differin. *See* Adapalene
Diffuse alopecia, 2747*t*, 2748
Diffuse alveolar damage, 650
chest radiograph of, 520*f*
Diffuse alveolar hemorrhage, 566*t*, 568
clinical manifestations of, 568, 568.e1*f*
definition of, 568
diagnosis of, 569, 569*f*, 569.e1*f*
pathobiology of, 568
prognosis of, 569
treatment for, 569*b*
Diffuse bronchiectasis, 522
Diffuse cutaneous leishmaniasis, 2133
Diffuse cutaneous systemic sclerosis, 1777, 1777*t*
Diffuse esophageal spasm, 909, 909*b*, 909*f*
Diffuse homogeneous opacities, 520–521
Diffuse hyperpigmentation, 2743
Diffuse hypoxic injury, 2462
Diffuse idiopathic skeletal hyperostosis (DISH), 1706*t*, 1815
Diffuse infiltrative lymphocytosis syndrome, 2323
Diffuse large B-cell lymphoma, 1279, 1284, 1285*b*, 2315
subtypes of, 1285, 1285*b*
Diffuse lung disease, 520–524
Diffuse pleural thickening, 526
Diffuse proliferative lupus nephritis, 787*f*–788*f*
Diffuse reticular lung disease, chest radiograph of, 522*f*
Diffuse-type gastric cancer, 1340
Diffusely adherent *E. coli*, 1961, 1962*t*
Diffusing capacity, in pulmonary function tests, 528*t*, 530–531, 531*f*
Diflunisal
for amyloidosis, 1309*b*, 2560*b*
for chronic pain, 138*t*
DiGeorge syndrome, 347, 1679–1680, 1679*b*, 1679*t*
hypoparathyroidism and, 1661
Digestive decontamination, for health care-associated infections, 1867
Digital rectal examination, for gastrointestinal disease, 851
Digital subtraction angiography, in atherosclerotic PAD, 463, 463*f*
Digitalis overdose, treatment of, 752*b*

Discordant thyroid tests, causes of, 1497t
Discrete data, 36
Discrimination, in health care, 42
Disease(s)
  anatomic distribution of, 523
  changing patterns of, 23
  complement system in, 196, 198t
  gene therapy for, 175–176
  genetic architecture of, 158, 158f
  global burden of, 21f, 23
  nutrition and, 57–60
  in older adults, 114–115
  stem cell-derived platforms for modeling of, 174
  trajectories of, 12.e1f
Disease-modifying antirheumatic drugs (DMARDs), 144, 1717, 1755b, 1756t, 1830.e1t
Disease-modifying medical therapy, for myelodysplastic syndromes, 1255
Disease-related malnutrition, 1447, 1447f
Disequilibrium dizziness, 2647t
DISH. See Diffuse idiopathic skeletal hyperostosis
Disoproxil fumarate, 2301t
Disopyramide, e10t–e11t, 283f, 325t
Dispersion, 36
Dissecting cellulitis, of scalp, 2750
Disseminated candidiasis, 1861f
Disseminated cutaneous leishmaniasis, 2133
Disseminated gonococcal infection, 1849, 1949–1950
  clinical manifestations of, 1949, 1949f
  diagnosis of, 1950
  prevention of, 1950
  prognosis of, 1950
  screening of, 1950
  treatment of, 1950b
Disseminated histoplasmosis, 2082, 2083b
Disseminated infections, 2090
Disseminated intravascular coagulation (DIC), 1178, 1195–1198
  causes of, 1195, 1195t
  clinical manifestations of, 1195–1196, 1196f
  definition of, 1195
  description of, 2696f
  diagnosis of, 1196
  management of, 2269b
  pathobiology of, 1195, 1196f
  treatment of, 1196b, 1197t
Disseminated mucormycosis, 2099
Disseminated nontuberculous mycobacterial disease, 2045
Distal acquired demyelinating symmetric neuropathy, 1296
Distal acquired demyelinating symmetric syndrome, 2576, 2576b
Distal acquired demyelinating syndrome, 2574, 2576b
Distal axonopathy, 683–684
Distal renal tubular acidosis, 749t, 761, 816t, 817, 818b, 818t
Distal subungual onychomycosis, 2754, 2754f
Distal symmetrical and autonomic polyneuropathy, 2577, 2577b
Distal symmetrical peripheral polyneuropathy, 2313
Distal tubule
  disorder of, 816t, 817
  diuretics, 736b
Distention
  abdominal pain and, 856
  bloating and, 859, 859b
Distinctive lesions, in black skin, 2744, 2744t
Distorted vision, 2599
Distributive shock, 658, 659, 659f, 661t
Disulfiram, for alcohol use disorders, 2357b, 2358t
DITRA. See Deficiency of the IL-36R antagonist
Diuretics
  for heart failure, 265b
  for hypertension, 454
  for hypervolemia, 736b, 736.e1f, 737t
  hypokalemia and, 749t
  for postpartum diuresis, 288b
Diverticular bleed, 884
Diverticular disease, 60, 954, 954.e1f, 955b, 955f
Diverticulitis, 955b, 955f
  abdominal pain and, 854t
  colitis, 956
  colonic, 954, 954.e1f, 955f
Diverticulosis, colonic, 954, 954.e1f, 955b, 955f
Dix-Hallpike test, 2646
Dizziness
  description of, 303, 2371, 2372f, 2646, 2647t
  evaluation of, 2646
  with palpitations, 303f
DKA. See Diabetic ketoacidosis
DMARDs. See Disease-modifying antirheumatic drugs
DNA hypomethylating agents, for myelodysplastic syndromes, 1255
DNA recombination, defects of, 1681t
DNA testing, 165
DNase, 625b
DOACs. See Direct oral anticoagulants
Dobrava-Belgrade virus, 2265t
Dobutamine
  for right ventricular infarction, 384b
  for shock, 664t, 667b, 672
Docetaxel (Taxotere), 1215t
  for head and neck cancer, 1327b
  for soft tissue sarcomas, 1389b
DOCK2 deficiency, 1678, 1678.e1t
DOCK8 deficiency, 1678, 1678.e1t
Docosanol, for herpesvirus infections, 2189
Doctoring, 3
Documented symptomatic hypoglycemia, 1546t
Doege-Potter syndrome, 526
Dofetilide, 325t
Döhle body, peripheral blood smear of, 1071f, 1072–1073
Dolasetron, for nausea and vomiting, 863t
Doll's eye test, 2646
Dolutegravir, 2301t
Domperidone, for intestinal pseudo-obstruction, 889b
Donabedian triad, 44, 44t
Donath Landsteiner test, 1088
Donation after cardiac death (DCD), 844
Donepezil
  for Alzheimer disease, 2416b
  for Parkinson disease, 2487t
Donor lymphocyte infusion, 1207
Donovanosis, 2004–2005, 2004b, 2004f
Dopa-responsive dystonia, 2493
Dopamine
  neurotransmitter, 143
  prolactin inhibition by, 1477–1478
  for shock, 662b, 664t, 673b–675b
  synthesis of, 1529
Dopamine agonist therapy, for Parkinson disease, 2486b
Dopamine receptor antagonists, for nausea and vomiting, 863t
Doppler echocardiography, 236–238
  color flow imaging, 236
  continuous-wave, 236
  modalities, 236

  continuous-wave, 236
  for gallbladder cancer, 1054
Doppler ultrasonography *(Continued)*
  pulsed, 236
  renal artery stenosis for, 800
Doravirine, 2301t
Doripenem
  dosage of, 1895t
  for pyelonephritis and urosepsis, 1877t
  for pyogenic liver abscess, 1023b
Dorsal midbrain syndrome, 2619
Dorsal root ganglionopathy, 2567t
Dot-in-circles sign, 2110–2111
Double-blinded controlled trial research design, 36
Double-contrast barium enema, 1353
Double density sign, 245, 245f
Double-hit and gray-zone lymphomas, 1285, 1285b
Double vision, 2598
Down syndrome, 164, 347, 2548f, 2549
  neutrophilia and, 1142
  treatment for, 2549b
Downbeat nystagmus, 2619
Doxazosin, 451t, 824t
Doxepin, 2452t
Doxepin + nordoxepin, e10t–e11t
Doxorubicin (Adriamycin, Rubex, Doxil), 1215t
Doxycycline, 2115
  for American monocytic ehrlichiosis, 2061b
  for anthrax exposure, 97
  for bacillary angiomatosis, 2003b
  for brucellosis, 1987b
  for cholera, 1956b, 1957t
  dosage of, 1895t
  for endocarditis, 2003b
  for granuloma inguinale, 2004b
  for intestinal bacterial overgrowth, 934b
  for leptospirosis, 2031b
  for Lyme disease, 2026t
  for malaria, 2112t, 2121t, 2123t
  for nontuberculous mycobacterial disease, 2046t
  for pelvic inflammatory disease, 1883t
  for plague, 98b, 1991b, 1992t
  for pneumonia, 613t
  for psittacosis, 2012b
  for Q fever, 2063b
  for relapsing fever, 2028b
  for rickettsialpox, 2060b
  for Rocky Mountain spotted fever, 2057b
  for scrub typhus, 2060b
  for syphilis, 2019
  for tick-borne rickettsioses, 2058b
  for total knee arthroplasty, 1830.e1t
  for tularemia, 99b
  for urethritis, 1880t
DPP4. See Dipeptidyl peptidase 4
DPYD gene, 160t
Dracunculiasis, 2180
DRB1*0301 allele, 204
DRESS. See Drug rash with eosinophilia and systemic symptoms
DRESS syndrome, 792
Dressings, for skin diseases, 2697
Dressler syndrome, 626
Driving, heart failure in, 265b
Dronabinol, for nausea and vomiting, 863t
Dronedarone, 325t
Droopy eyelid, 2600, 2600f
Droperidol, for nausea and vomiting, 863t
Dropped head syndrome, 2563
Drowning, 591–592, 592b
Droxidopa, for orthostatic hypotension, 2559t
Drug(s)
  absorption of, 126
  of abuse, 143
  acid peptic disease caused by, 917
  acquired platelet dysfunction caused by, 1185
  acute pancreatitis and, 970, 970t
  administration of, 126
  adverse reactions to, 131
  antiarrhythmic, 313b
  for atherosclerotic cardiovascular disease, 1410
  bioavailability of, 126
  bone loss as caused by, 1641
  classes of, 1898
  clearance, 127
  decreased excretion of, 131
  decreasing level of, 128
  determining accumulation of, 128, 128f
  distribution of, 126

Whipple disease, 417*t*, 937, 1821, 2069–2071
  classical, 2070, 2070*t*
  clinical manifestations of, 2069–2070
  definition of, 2069–2071
  diagnosis of, 2070, 2070*f*, 2071*f*, 2072*f*
  epidemiology of, 2069
  pathobiology of, 2069
  pathogen that causes, 2069
  prevention of, 2071
  prognosis of, 2071
  treatment for, 2070*b*
Whisper test, 117
White blood cell count (WBC), ranges of, 1140
White coat hypertension, 447
White heads, 2722
White superficial onychomycosis, 2754, 2754*f*
WHO. *See* World Health Organization
WHO/ISUP. *See* World Health Organization/International Society of Urologic Pathology
Whole blood, HIV transmission through, 2299
Whole-body exposure syndromes, treatment of, 94*b*, 94*f*
Whole bowel irrigation, for acute poisoning, 691*b*
Whole-lung lavage, for pulmonary alveolar proteinosis, 567*b*, 567.*e1f*
Whole pancreas transplantation, for type 1 diabetes mellitus, 1537*b*
Whooping cough
  chemoprophylaxis for, 1996
  clinical manifestations of, 1995
  complications of, 1995
  definition of, 1994–1996
  diagnosis of, 1995
  epidemiology of, 1994–1995
  immunizations for, 1996
  pathobiology of, 1995
  pathogens that cause, 1994
  prevention of, 1996
  prognosis for, 1996
  treatment of, 1995*b*
Widow spiders, envenomation of, 710
Wiggers diagram, 225.*e1f*
Williams syndrome, 348, 1658
Wilson disease, 816*t*, 993, 999, 1398*t*, 1436–1437
  clinical manifestations of, 1436–1437, 1436*f*, 1437*f*
  definition of, 1436–1437
  diagnosis of, 1437
  dystonia *versus*, 2493
  epidemiology of, 1436
  pathobiology of, 1436
  in pregnancy, 1625*t*
  prognosis of, 1437
  treatment of, 1437*b*
Wiskott-Aldrich syndrome, 1071, 1144, 1179, 1678–1679, 1678*b*, 1679*t*
Wiskott-Aldrich syndrome protein (WASP), 1736–1737
Withdrawal of life support, 638, 638*t*, 638.*e1t*
WNK kinases, 746
Wnt signaling pathway, 1640
Wohlfart-Kugelberg-Welander disease, 2565
Wolbachia bacteria, 2061–2062
Wolff-Parkinson-White syndrome, 229, 306, 326
Women's health, 1606–1610
  alcohol use, 1609
  anxiety disorders, 1608*t*, 1609
  cancer, 1607
  cardiovascular disease, 1606
Women's health *(Continued)*
  depression, 1608*t*, 1609
  health disparities in, 1606
  human immunodeficiency virus, 1609
  incontinence, 1609
  lifespan groups for, 1606, 1606*t*
  medications for, 1608*t*
  morbidity causes, 1609
  mortality causes, 1606
  obesity, 1609
  osteoarthritis, 1609
  osteoporosis, 1607
  risks for atherosclerotic cardiovascular disease, 221.*e1f*
  severe acute respiratory syndrome coronavirus 2, 1610
  smoking, 1609
  substance use, 1609
  type 2 diabetes, 1607
  urinary tract infection in, prophylactic regimens for, 1877*t*
Women's Health Initiative, 1630*b*
Wood alcohol, 760
Work-exacerbated asthma, 586
  clinical manifestations of, 586–588
  diagnosis of, 586*b*
  epidemiology of, 586
  treatment of, 586*b*
Work of breathing, 641, 641*f*
Work-related asthma, 585
  clinical evaluation of, 587*f*
  management of, 587*f*
  occupations at risk for, 586*t*
Work-related disability, 85
Workers' compensation, 85
World Health Organization (WHO)
  classification of Hodgkin lymphoma, 1290*t*
  mastocytosis
    classification of, 1699*t*
    disease categories, 1702, 1702*t*
  on myelodysplastic syndromes, 1252
  non-Hodgkin lymphoma, 1279
  rubella, 2224
  sexually transmitted infection estimates, 1879
  on tuberculosis, 2032
World Health Organization/International Society of Urologic Pathology (WHO/ISUP), 1366
Wound
  botulism of, 1927
  infection
    Acinetobacter causing, 1973
    in endoscopy, 876*t*
  tetanus prophylaxis in, 1929*t*
Wrist
  disorders of, 1745
  fractures of, osteoporosis and, 1607
  rheumatoid arthritis of, 1751, 1753*f*
  surgical treatment of, 1828
Wuchereria bancrofti, 2176

X

X chromosome mutation, in premature ovarian failure, 1600
X-inactivation, 162
X-linked agammaglobulinemia, 1681*t*
X-linked hypophosphatemia, 1648
X-linked ichthyosis, 2687.*e3t*
X-linked lymphoproliferative syndrome, 2254
X-linked proliferative disorder (XLP), 1684
X-linked protoporphyria (XLP), 1428*t*, 1433
X-linked severe combined immunodeficiency, 175, 1676.*e3t*, 1678
X-linked thrombophilia, 476
Xalkori. *See* Crizotinib
Xanthelasma, 987, 2692*t*
Xanthine oxidase, 1810
Xanthogranuloma family, 1157–1158, 1158*b*
Xanthogranulomatous pyelonephritis, 791
Xanthoma disseminatum, 1157
Xanthomas, 216, 216.*e1f*, 1823
Xeljanz. *See* Tofacitinib
Xeloda. *See* Capecitabine
XEN402, 471*b*
Xenografts, 203
Xenopsylla cheopis, 1988
Xenotransplantation, of genetically modified animals, 172
Xerocytosis, 1097
